THE BLACKWALL TUNNEL BENEATH THE THAMES.

THE Blackwall Tunnel, which easily takes rank as one of the great engineering works of the age, was formally opened for public use on May 22 last in the presence of their Royal Highnesses the Prince and Princess of Wales, the London County Council, and other dignitaries.

The story of the difficulties, seen and unforeseen, encountered in carrying out this great undertaking can best be told in the words of the engineers who were in immediate charge of the work. By the courtesy of Mr. Maurice Fitzmaurice, one of the resident engineers, we are enabled to present the following extract of a paper read by himself and Mr. David Hay, members of the Institution of Civil Engineers, before the meeting of the Institution held April 6, 1897.

About the year 1875 it became generally recognized that the construction of more river crossings below London Bridge could not be further delayed, and the matter was taken up by the Metropolitan Board of Works, who brought forward several schemes both for bridges and tunnels; but it was not until 1887 that the Blackwall Tunnel Act was obtained. The design, as proposed by Sir Joseph Bazalgette, consisted of three tunnels, two for vehicular traffic and one for foot passengers; and it was determined to construct the latter in the first instance. The internal diameter was to be fifteen feet, and the tunnel was to be made of cast iron, and to be lined with brickwork. Tenders for this work were invited, and it was decided to let it to Messrs. S. Pearson & Son; but owing to the Metropolitan Board of Works being replaced by the London County Council, and the latter body considering that a larger tunnel ought to be made at once, the contract was never carried out. It was then three years before the final decision was made, and at the end of 1891 the contract for the present tunnel was obtained by Messrs. S. Pearson & Son, the amount of their tender being $4,215,640. The total length of the tunnel is 6,200 feet, 1,220 feet of which are below the river. The lengths adopted for each type of construction are shown in Fig. 2, that of the east iron lined portion being 3,112 feet.

NORTHERN ENTRANCE TO THE TUNNEL.

OPEN APPROACHES.

The open approaches on each side of the river extend from the ends of the cut and cover work to the points where the roadway attains the existing road levels. The construction adopted consists of concrete and brick retaining walls with a concrete invert between them. On the Middlesex side the excavation was almost entirely in clay or made ground, and there was little difficulty with water. On the Kent side the work at the deep end was almost wholly in water-laden ballast. The side walls were first built in timbered trenches, and the dumpling was afterward excavated and the invert inserted. The brickwork has a white glazed face and is bonded into the concrete, being alternately 9 inches and 18 inches thick, in equal lengths of 3 feet. As water tightness was absolutely necessary, the walls were coated with 1½ inch of asphalt, which was carried down the back to within three feet of the bottom and thence across through the invert. This gave a continuous water tight layer completely surrounding the work, which has proved satisfactory.

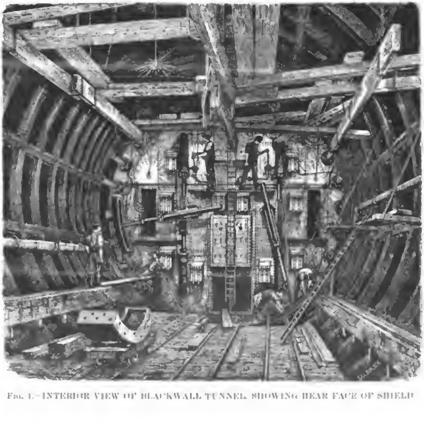

FIG. 1.—INTERIOR VIEW OF BLACKWALL TUNNEL SHOWING REAR FACE OF SHIELD.

CUT AND COVER PORTION.

The first section of the cut and cover portion consisted of four layers of brickwork, built in concentric rings, surrounded by a band of asphalt 1½ inch thick, and by 6 to 1 cement concrete which was backed up by clay puddle. The puddle backing, however, was found unsatisfactory, notwithstanding the fact that it was rammed as stiff and solid as possible, as the side walls began to spread slightly when the filling was placed on the arch. To prevent further movement, piles were driven through the filling into the puddle, the use of which was thereafter discontinued and another section substituted. The concrete was built tight to the sides of the trench, and the asphalt was mainly relied upon for water tightness. The arch on the Middlesex side was also built to this section. In the deeper part of the cut and cover portion substituted for the iron lined tunnel, on the Kent side, an extra ring of brickwork was added.

SHAFTS.

There are four shafts in the line of the tunnel; Nos. 1 and 2 situated on the north side, and Nos. 3 and 4 on the south side of the river. Their positions, Fig. 2, were determined by the horizontal or vertical changes of direction of the tunnel, which was driven straight from shaft to shaft, the difficulty of driving the shield on a curve and the trouble and expense of special castings being thereby avoided.

Caissons.—The caissons, Figs. 8 and 9, are 48 feet in internal and 58 feet in external diameter, and are formed of two skins, partly of steel and partly of iron. The plates, generally 4 feet in depth, vary in thickness between ⅜ inch at the bottom and ⅝ inch at the top. The lower portion is constructed of steel to 8 feet 6 inches above the cutting edge. The space between the skins, 5 feet near the cutting edge and reduced by the outside batter to about 4 feet at the top, is filled with 6 to 1 Portland cement concrete. There is an internal lining of brickwork with a glazed face, the finished diameter of which is 45 feet 8 inches. The floors of shafts are formed of 6 to 1 concrete 11 feet thick.

Two openings are formed in each shaft, 29 feet 4½ inches in diameter, on the center line of the tunnel, and the caisson is strengthened round them by vertical and radial diaphragms. These openings were closed during the sinking by iron shutters bolted together so as to be readily removable in sections capable of being passed through the advancing shield.

Arrangements were made for attaching airtight floors to the inner skin of caissons, above the level of the tunnel openings, for use either in sinking the shafts or constructing the watertight floors, should compressed air be found necessary, and when it was required to drive the tunnel through. The floor consisted of ⅝ inch buckled plates resting on girders 15 inches deep; above these 4 foot girders were placed at right angles, the whole being surmounted by two girders 12 feet deep. When the air pressure exceeded 20 pounds per square inch above atmospheric pressure, the upward thrust on the floor was relieved by 10 feet or 14 feet of water ballast.

Method of Sinking.—The shafts on the south side of river were sunk by pumping down the water and removing the excavation from the inside in the ordinary way. The weight of caisson and concrete filling was generally sufficient to overcome the skin friction, until about 20 feet from the bottom, when more weight had to be temporarily added. The sinking of No. 4 shaft was accomplished without difficulty, but considerable trouble was experienced in dealing with No. 3 at the river bank. The ground for about 25 feet of the lower part of the shaft is composed of fine sand, and numerous "blows" were caused by the head of water in the ballast above (charged afresh by every tide), washing in large quantities of gravel and sand. The ground was of such a heavy, clinging nature that the caisson was often stationary for several days, although the cutting edge was free and the structure was heavily loaded; and it was not until a blow occurred, the movement of the ballast decreasing the skin friction, that further downward progress could be made. The caisson was at one time 14½ inches out of level, and various expedients were tried to induce blows on the high side in order to correct it. The best results were obtained by striking heavily on the

inside of the shaft with a balk of timber swung horizontally from a girder above.

As all the weight had been placed on the skins for which room could be found, the girders of the air-tight floor were fixed and loaded; better progress was then made, and when the top water was cut off no difficulty was encountered in dealing with the springs in the sand below the London clay; the floor was therefore constructed, as in the case of No. 4, without the aid of compressed air. The friction on the outside skin for the last 30 feet in the case of No. 3 amounted to about 675 pounds per square foot, the cutting edge being entirely free.

On the north side of river No. 2 shaft was sunk behind a new river wall (Fig. 2), which had been built to reclaim part of the foreshore. The whole of the ground to be penetrated consisted of ballast; and it was decided to employ a grab for the excavation, allowing the water to remain inside. The total weight of the caisson and sinking load amounted to nearly 4,000 tons, the skin friction being therefore about 500 pounds per square foot of outside surface.

The first 28 feet of No. 1 shaft were sunk in the same manner as Nos. 3 and 4, but on reaching this depth, large quantities of water were encountered, and the grab system was again used. This method was continued until the cutting edge had passed through the ballast and sufficiently far into the clay below to cut off the top water. The water inside was then pumped out and manual labor was again employed. Ultimately it was found necessary to construct the air-tight floor and carry the caisson down by the pneumatic process.

IRON LINED PORTION OF THE TUNNEL.

For about one-third of the distance across the river the tunnel had to be constructed through a bed of open ballast in direct communication with the river, and it was assumed that the pressure of air in this portion of the tunnel would have to be equal to that due to the head of water. It was not considered advisable for men to work in a pressure exceeding 35 pounds per square inch above atmospheric pressure. This maximum air pressure corresponds to a depth of 80 feet of water, and the bottom level of the tunnel was therefore placed at 80 feet below Trinity high water, or 67.50 below Ordnance datum. The tunnel had to be of sufficient diameter to allow a line of traffic in each direction and give two paths for foot passengers. A diameter of 27 feet was considered the minimum which would give sufficient accommodation for the traffic, and the top was thus within 5 feet of the bed of the river in the deep channel, the ground between the top of tunnel and river bed being open ballast.

Without the cast iron lining a great portion of the tunnel would have been almost impossible. In addition to its necessity as a support, at once solid, from which to shove the shield forward, the following points are to be considered:

(1) The work attains its full strength as soon as it is erected, and the difficulty in keeping pressure off green brickwork is avoided.

(2) The facility with which it can be erected. On some occasions 12 feet 6 inches of tunnel have been completed in 24 hours, and during that time only 7 hours was occupied in erecting the iron.

(3) A smaller thickness of lining is necessary than with brickwork, with correspondingly less excavation.

(4) The tunnel can be made absolutely watertight from the inside by calking.

(5) By immediately filling the space left by the shield at the back of the cast iron lining settlement is rendered impossible.

Two sections of lining have been used, both 27 feet in external diameter. The first consists of a tube 2 inches thick, having flanges 12 inches deep and between 2 inches and 3 inches thick; and the second is 1½ inch thick, with flanges 10 inches deep and between 1¾ inch and 2½ inches thick. The rings of both sections are 2 feet 6 inches in length, and are built up of 14 segments, about 6 feet long circumferentially, and a solid key at the top, together weighing about 14 tons 16 cwt. and 10 tons 10 cwt. in the heavy and light sections respectively. All joints are machined and the segments are joined without any packing between them. Recesses are formed on the inside of the flanges for calking, and the joints are thus made perfectly watertight. Holes, 1½ inch in diameter, are drilled and tapped in each segment for grouting, and were closed with screw plugs when grouting was completed. The segments are fixed together with 1¼ inch bolts of the various lengths required, each being provided with a grummet.

THE SHIELD.

The shield, which is constructed of steel, is shown in Figs. 1 and 6, and was designed by Mr. E. W. Moir, M. Inst. C.E. The problem which the contractors had to deal with in its design was complex, and the satisfactory completion of the tunnel shows the success with which the situation was met. It was known that the ground to be passed through consisted of clay, sand and ballast, that there were probabilities of meeting large bowlders, and that the hard beds forming the base of the London clay would be encountered. In London clay a shield with an open face was desirable, and one was required in which the whole or any part of the face could be closed in the ballast under the river channel. Provision had also to be made for the removal of bowlders, trunks of trees, or other obstacles in front of the shield. Its strength should be sufficient to resist all possible pressure which might come on it either when compressed air was or was not in the tunnel and shield, or when there was compressed air

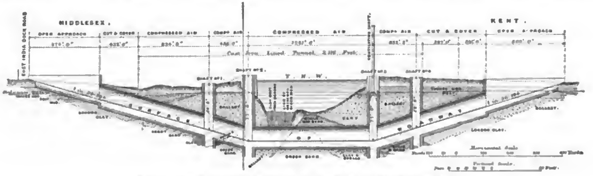

FIG. 2.—LONGITUDINAL SECTION ON CENTER LINE OF TUNNEL.

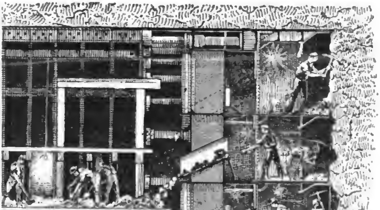

FIG. 6.—SECTIONAL VIEW OF HYDRAULIC SHIELD.

in front of the shield and not in the tunnel. Sufficient strength was also required to take up the maximum pressure from the rams at the back when it was necessary to force it forward; bearing in mind the fact that the pressure of the rams might be more or less unequally distributed, owing to some rams being shut off at times in order to correct any deviation from line or level. In addition to these requirements every precaution had to be taken to insure the safety of the men working at the face.

The total length of the shield was 19 feet 6 inches, and the outside diameter was 27 feet 8 inches. The outer shell or skin, 2½ inches thick, consisted of four thicknesses of ⅝ inch steel plates, twenty-eight plates extending the full length of the shield to each ring, and, consequently, all the joints were longitudinal. In some previous shields cross joints had been adopted,

MAURICE FITZMAURICE, M.I.C.E., RESIDENT ENGINEER OF THE BLACKWALL TUNNEL.

and the plates had been ripped up at these joints. The plates in the different rings broke joint with each other, and all the rivets were countersunk on the outside.

The first portion of the inner shell, beginning at 6 feet 8 inches from the rear end of the shield and extending forward for a length of 6 feet, was 24 feet in diameter, and consisted of a ¾ inch plate, the space between it and the outer skin forming cells for the hydraulic rams. The second portion was 25 feet 3 inches in diameter, and was made of ⅝ inch plate. This portion takes up a certain amount of the thrust of the hydraulic rams, and is sloped down to meet the outer skin near the face, but the actual cutting edge was formed of the outer skin only. The outer and inner skins were strongly braced together by circular girders; in the webs of the two rear of which, holes were cut for the passage of the ram cylinders. The forward half of the shield was stiffened by three horizontal and three vertical plate diaphragms which also served to divide the working face into four floors and twelve compartments. There were two plate diaphragms stiffened by vertical girders at right angles to the axis of the shield, one placed at about the center of the shield and the other about 3 feet behind it. Access to the second and bottom floors was provided for by hatchways from the floors above, but in the case of the bottom floor two plates in the diaphragm were afterward removed, and doors were fixed to allow of direct access from the tunnel.

An inclined soil shoot, fitted with rubber faced doors at each end, was provided for each of the twelve compartments, but the doors, like those for the air locks, were never required except for closing the face in emergencies. At 6 feet 7 inches back from the cutting edge were placed the vertical iron screens previously referred to.

The rear end of the shield for a length of 6 feet 8 inches consisted of the outer skin only, and in this tail the tunnel segments were built. The tail was long enough to always envelop the last ring erected, even when the shield was shoved forward far enough to give room for the erection of the next ring. At the extreme end of the tail there was a bead or curved narrow plate extending round the inside. This allowed more working space for the adjustment of the ring to be erected, and at the same time permitted greater freedom in deflecting the shield if for any reason it was required to change its direction.

The number of hydraulic rams originally provided for advancing the shield was twenty-eight; they were 8 inches in diameter and had a stroke of 4 feet; but while driving through the wet sand and ballast under the river this number of rams was found insufficient, and was therefore increased by six other rams, 10 inches in diameter, but with a shorter stroke. The maximum water pressure used was about 2¼ tons to the square inch, or a total, when all the rams were employed, of 5,165 tons, making no allowance for the friction of the rams.

Two hydraulic erectors, Figs. 1 and 10, for lifting the tunnel segments into place, were carried on the back of the shield. The circular motion of the arm was obtained by a rack on a piston working vertically between two hydraulic cylinders which revolved a pinion on which the arm was fixed. A movable arm was lengthened or shortened by another jack fixed on the base of the arm, and a small movement in the plane of the length of the tunnel was obtained by a tangent screw near the pinion. A water pressure of 1,000 lb. to the square inch was used for working the erectors. In Fig. 1 one of these erectors is shown lifting a segment into place.

DRIVING THE TUNNEL.

After the shield had been placed in the tunnel opening of No. 4 caisson (in which cast iron guides had been bolted to insure true line and level being followed), a portion of the cast iron lining, extending to the other side of the shaft, was temporarily built up behind the shield to form an abutment for the hydraulic rams in driving the shield forward. The plug was then removed from the tunnel opening (Figs. 8 and 9), and the shield began its forward movement.

At first progress was somewhat slow, only 125 ft. being driven in the first two months, but after the gravel disappeared and the top heading was discontinued, better progress was made, an average length of 25 ft. being completed per week. An accident, however, soon after happened to the shield which caused some delay. At the base of the London clay, and in the sand immediately below it, large pieces of rock were embedded and considerable damage was caused to the cutting edge by driving against them, and, after 80 rings had been erected, the shield was found to be unworkable. As it was not practicable to repair it in its then position, it was decided to construct a concrete cradle for it to slide upon. A timbered heading, 19 ft. wide, was therefore driven and kept about 50 ft. in advance of the shield, so that the concrete should have time to become hard before the shield came upon it. During the driving of this heading trouble was again experienced from water in the ballast above finding its way through cracks in the clay, and the top heading was accordingly recommenced, so as to intercept the water and carry it through the shield. This method of working was continued until No. 3 shaft was reached, where the repairs to the shield were effected.

R. W. MOIR, M.I.C.E., ENGINEER FOR THE CONTRACTORS.

On the arrival of the shield at No. 3 shaft it became necessary to undertake the repairs required on account of the buckling of the cutting edge. It was decided to cut away the distorted portions of the skins and vertical stiffener, Fig. 3, and substitute heavy steel castings, as shown in Fig. 5. At the same time the projecting plates of the undamaged part of the cutting edge were cut off, and, although sharpness was thereby lost, the edge was much stronger to sustain a blow against any obstacle in front. The steel castings were made to a larger radius than the outside skin, so that they should stand "proud" of it and thus decrease the skin friction when the shield was being pushed forward. A steel band, ⅝ inch thick, was also carried round the outside of the undamaged part of the cutting edge, with the same object, and to further strengthen it. Most of the repairs were executed in the ordinary atmosphere; they were commenced on May 28, and completed on August 25, thus extending over a period of thirteen weeks. In carrying out the repairs a great number of holes had to be drilled, and flexible shafts driven by electric motors were used to great advantage. The motors were fixed in the shield and current was supplied from dynamos on the surface.

Under the River.—The portion of the tunnel between No. 2 and No. 3 shafts includes all the work actually beneath the Thames. The length from center to center of the shafts is 1,222 feet. There is a layer of London clay between the tunnel and the river bed for nearly three-fifths of the distance; the clay is then lost, and what was probably an older and deeper bed of the river, now filled with ballast, was met with (Figs. 2 and 7). As was anticipated, the work was carried out expeditiously, and without difficulty in maintaining a sufficient pressure of air as long as the clay cover continued. In starting from No. 3 shaft the upper part of the shield was in clay and the lower part in sand. The rate of progress here surpassed that in any similar tunnel yet constructed. In two months more than 500 feet of tunnel were completed, and occasionally five rings, or a length of 12 ft. 6 in., were constructed in 24 hours. During a day, therefore, 300 cubic yards of material was excavated and about 75 tons of cast iron erected. When it is considered that these materials, in addition to lime, other necessaries and empty wagons, had to pass through

SOUTHERN ENTRANCE TO TUNNEL.

the air locks, it will be apparent that very careful organization on the part of the contractors was required.

In penetrating the old river channel the shield passed within about 5 ft. of the bed of the river, the material above being open ballast. Previously to reaching this point permission had been obtained from the Thames Conservancy to tip a temporary layer of clay on the river bed for a length of 430 ft. in the line of tunnel. Its maximum depth was 10 ft., and it extended 75 ft. on each side of the center line. It offered resistance to the air escaping from the tunnel through the open ballast, and its weight prevented the bed of the river from being blown up by the pressure. The clay was deposited from hopper barges, and was removed as the tunnel was completed.

The shutters for closing the face of the shield, Fig. 1, were invaluable when passing through ballast or any open material. As the face had to be kept closed while the shield was being moved forward, it was evident that they must have a sliding movement, so as not to become broken up when the shield was advancing, as would be the case if the face was timbered in the usual way. In each compartment of the three upper floors there were three shutters. They varied in depth between about 2 ft. 3 in. and 1 ft. 6 in., and were of varying lengths to suit the different compartments. Each consisted of a ⅜ in. iron plate, stiffened at the edges by heavy angles, and sliding on guides fixed to the sides of the compartment. The shutters were controlled by long screws, fixed to their ends and extending through bearings on the side of the compartment.

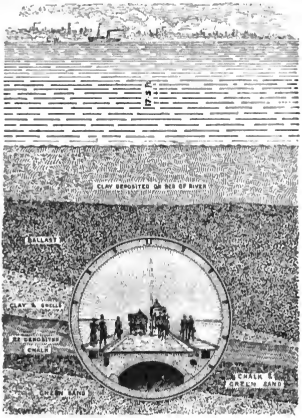

FIG. 7.—CROSS SECTION OF THE RIVER THAMES, SHOWING THE FINISHED BLACKWALL TUNNEL.

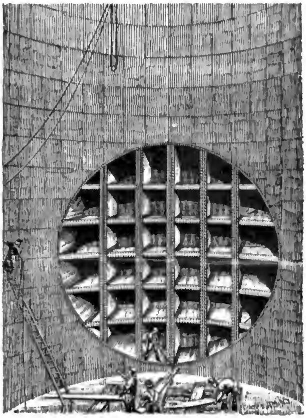

FIG. 8.—BOTTOM OF CAISSON, SHOWING TEMPORARY PLUG.

In the ballast, previously to shoving the shield forward, the face of a compartment was completely closed by its three shutters which had been screwed forward as close to the cutting edge as possible, the shutters being directly over each other, and the small space between them being filled with clay. When the shield was to be shoved forward the nuts on the screws were loosened on the forward side of the bearings, allowing the shutters to move back as the shield was shoved forward. Any sudden movement was guarded against by running the nut only 1 in. or so in front of the bracket at a time.

The method and rate of removal of this material depended on the consistency of the ballast, and whether the air pressure in the tunnel was sufficiently high. Under favorable circumstances the ballast might be shoveled out from the top of the shutters, or a shutter might be drawn somewhat further back and the material shoved out between that shutter and the next lower one; but in any case the top shutter was first excavated and screwed forward, and then those at the middle and bottom.

The sliding shutters were not used in the two bottom pockets, and in their place a combination of long horizontal iron piles and short vertical timber piling, Fig. 5, was adopted. By this arrangement it was possible to clear out the ballast up to the cutting edge, which could not be done with the shutters. Great difficulty was experienced in the bottom floor, and the men working here were generally standing in about 18 in. of water throughout the day. Perforated tunnel plates were occasionally built in to relieve the water at the face by allowing it to enter the tunnel further back. Jets of high pressure water were used at times at the face to keep the material moving while the shield was advancing, to diminish the pressure required to shove the shield forward. Small shots were also used to shake the ground and to remove any hard material; and a man was constantly employed testing the face with a bar in front of the shield to discover any large bowlders which might damage the cutting edge.

The difficulties encountered while driving through ballast suggest modifications in shields for tunneling similar material. The shutters should be placed as close as possible to the cutting edge, and their area in relation to that of the face should be as large as possible. Much of the difficulty in driving the shield was due to this difference of areas; it would probably be little felt in passing through soft material which flows easily, but in gravel the resistance from this cause is very great. Such modifications would probably necessitate a heavier shield, but great improvement in working would result. It would also be well to allow for a large increase in the power required for shoving the shield over that anticipated, as it is difficult to even roughly estimate it when it is necessary to work with a closed face.

An airtight hanging screen was always fixed a short distance behind the shield to insure the safety of the men. It reached down to the center of the tunnel and was fitted with an air lock at the top, the doors of which were hung to open toward the bulkhead; this could be reached by a gangway which was added to as the shield advanced. In the event of an inrush of water, the men could thus escape to the other side of the screen, where they would always find an air space, and thence, by a gangway, to the emergency lock in the bulkhead.

Serious "blow outs" occurred while working in the ballast, and on two occasions the air pressure fell so suddenly, and the water from the river poured in so fast in the two upper floors that the tunnel was flooded to a depth of 7 or 8 feet in a few seconds. The first of these blows occurred on the 30th of April, 1895, and the second and largest about a week later, when about three-quarters of the distance across the river had been covered. The escape gangway had not at that time been provided, and, owing to the dense fog, caused by the sudden fall of air pressure, completely

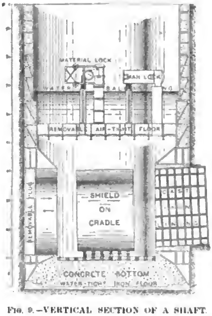

FIG. 9.—VERTICAL SECTION OF A SHAFT.

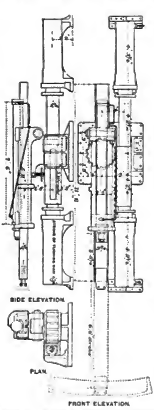

FIG. 10.—DETAILS OF HYDRAULIC ERECTORS.

obscuring the electric lights, the men had difficulty in escaping back to the lock, then distant about 700 feet. The clay which had been placed on the bed of the river was then of the greatest possible value; it followed down upon the ballast, which was washed in by the water as through a funnel, and, choking the passage, the air pressure soon increased. The immediate cause of these accidents would appear to have been the breaking down by the rising tide of a large area of the hard crust on the river bed left unsupported by runs of ballast from beneath it. Great care was afterward taken to look out for and fill such cavities with sawdust. This material was found to be very convenient for the purpose, the escaping air carrying it into the cavity through the hand holes in the sliding shutters. It will be noticed that for a length of 190 feet the river crust continued to break away and allowed the clay, deposited on the river bed, to enter the shield; but as long as there was no cavity, and consequently no liability of a large area of crust suddenly giving way, no danger was to be apprehended. In addition to carefully watching out for cavities in the front of the shield inside the tunnel, soundings were taken in the river in front of the shield every day to discover any subsidence of the clay. The cutting edge of the shield touched No. 3 shaft fifty-four weeks after the first ring was erected in No. 3 shaft.

Before removing the plug in the opening of No. 2 shaft, iron piles were driven from the inside of the shaft over the top of the shield, provision for this having been made in building the plug. The work of driving the shield into the shaft was then comparatively easy. The shield was found to be in as good condition as when it left No. 3 shaft, which, considering the severe treatment it received on its journey, speaks well for the excellence of its construction.

The air compressing plant, boilers, etc., were taxed to their utmost capacity during most of the work through the ballast, some of the compressors working with scarcely a stop for twelve months. Considerable repairs were consequently necessary before the tunnel beyond No. 2 shaft could be proceeded with. They occupied some weeks, and the contractors took the opportunity during the suspension of work to invite a number of visitors to celebrate the accomplishment of what must be considered the most difficult piece of subaqueous tunneling ever undertaken, luncheon being provided in the tunnel about midway across the river.

No. 2 Shaft to Railway.—Early in December work was resumed; the shield having been placed in position in the tunnel opening on the north side of the shaft, and the temporary iron lining built behind to take the thrust of the hydraulic rams, the airtight floor, which had been partly removed, was again closed, the air pressure applied and the plug removed. The face at this point, as under the latter part of the river, consisted entirely of ballast fully charged with water. The same difficulties were therefore met with both in removing the plug and for some distance in driving the tunnel, necessitating almost the same caution. Beyond small subsidences near the shaft, however, no accident occurred, and No. 1 shaft was reached on the 10th of April. A slight delay was occasioned at this point by the difficulties referred to in constructing the bottom floor of the shaft, but by the middle of May the shield had passed through and had been adjusted to the new line to be followed to join the "cut and cover" portion at the railway. A distance of about 800 feet remained, and it was accomplished by the end of September of the same year.

All the cast iron portion of the tunnel is lined with 4 to 1 Portland cement concrete and faced with white glazed tiles 9 inches by 3 inches to preserve uniformity of appearance with the brick facing in the cut and cover portion of the work. Throughout the cast iron lined tunnel and the cut and cover the roadway is carried on a 9 inch brick arch leveled up with concrete as shown in Fig. 7. The subway thus formed gives ample room for two large water mains or for a ventilating trunk if necessary. Provision is made for ventilation by building in at intervals pipes 2 feet 6 inches by 4 inches following the curve of the side of the tunnel and having an opening at the crown. These pipes are continued downward to the subway under the road, where they can be connected to a main ventilating pipe which can be exhausted by fans at shafts Nos. 2 and 3. The width of the roadway is 16 feet throughout, and there is a 3 foot footpath on each side of the tunnel increased to 5 feet 8 inches in the open approaches. The gradients of the approaches are 1 in 30 and 1 in 34 on the Kent and Middlesex sides respectively. The drainage of the roadway is taken by gullies 50 feet apart on alternate sides, and from thence it is conducted by 6 inch and 9 inch pipes to No. 2 shaft, and there it is pumped to the surface. The roadway for the level portion of the tunnel under the river is of asphalt, and for the approaches on each side granite sets laid in pitch and tar, the gradients on the latter portions being too steep for asphalt. For ordinary cart traffic access to the tunnel can only be obtained at the ends; but for the convenience of pedestrians stairways are provided at four other points, viz., at the junction of the "cut and cover" and "open approach" on each side of the river, and at Nos. 1 and 4 shafts.

MACHINERY.

There were six air compressors of a total capacity of about 1,300 horse power. The two largest, of about 300 horse power each, were manufactured by Messrs. Walker Brothers, of Wigan; two were made by the Ingersoll Company, of New York; one by the Haslam Engineering Company and one by Messrs. Slee. A smaller compressor was also in use for the air required for grouting purposes. During a large portion of the time, while passing through loose ballast, as much as 10,000 cubic feet of air per minute was sent into the tunnel. It was carried into the tunnel by steel riveted pipes 8 inches in diameter, taken down No. 4 shaft on the Kent side, and thence along the tunnel as completed to the end at the Middlesex side. When the air was escaping freely at the face, the amount pumped through these pipes was very large, and the velocity consequently very high. On this account the difference between the air pressure in the engine house and in the tunnel sometimes showed a loss of 40 per cent. It is evident that for a long tunnel it would be economical to have pipes of ample size, so that the velocity of air could be kept at say about 30 feet per second, as the extra cost of pipes would soon repay itself. The air for grouting purposes, the pressure of which was about 40 pounds per square inch greater than that for the tunnel, was carried in a 5 inch pipe. The high pressure water for the rams was carried in a steel pipe 1¼ inch in diameter, and as the end of the pipe was connected with the moving shield, a "walking joint" was used at some distance back from the face.

Electric incandescent lamps were used for lighting throughout the construction of the work to avoid vitiation of the atmosphere by lamps or candles as much as possible. An electric light installation has been erected on the Middlesex side of the river for the permanent illumination of the tunnel and also to supply current for working the drainage pumps and a small lift in No. 2 shaft. The tunnel will be lighted by three rows of incandescent lamps of 32 candle power, fixed 10 feet apart on alternate lines, with additional lamps and a few arc lights in the shafts. The open approaches will be lighted by groups of incandescent lamps.

The London County Council showed great interest in the health of the men employed in compressed air; and a stringent clause was inserted in the contract specifying among other particulars proper ventilation at the working face, the provision of lifts and resting places for the men, including a compressed air chamber fitted with locks, and that no workman should be engaged for compressed air work without his fitness for such duties being proved by previous experience or by medical examination. After the commencement of the work the Council obtained parliamentary powers to compensate men who might be injured by working in compressed air, although the men were not employed directly by the Council. A resident medical officer, Dr. E. H. Snell, was also appointed to examine all men previous to working in the compressed air, or who might be injuriously affected by it, and to thoroughly investigate the nature of compressed air illness. The cases of illness due to compressed air were few, and only three cases of permanent illness have been attributed to this cause, and there were no deaths. This is probably due to the fact that a sufficient supply of air was delivered, and that the men did not work in too long shifts. The general period of work was 8 hours, but there was a break of ¾ hour in this time as near the middle as possible. Hot coffee was supplied by the contractors to the men in the middle of their shift and also before coming out, and proper drying rooms with lockers were provided for their clothes.

COST.

The cost of work of this class is naturally of great interest; but the risks incident to tunneling in gravel within a few feet of the bed of a navigable river must generally render the contract cost of such works of uncertain value.

The cost of the completed work, as contracted for by Messrs. S. Pearson & Son, was $4,215,640, and, although there were some alterations from the contract quantities, the actual cost was below this amount. The contract price for heavy cast iron section was $630, and that for the light iron section $535 per lineal foot; the internal lining and roadway not being included in either case. The cost of the cut and cover portion, ranging in depth between 24 feet and 42 feet, was $295 per lineal foot; and for the portion ranging in depth between 42 feet and 65 feet, $535 per lineal foot, the roadway not being included in either case. The cost of the open approaches of an average depth of 35 feet below the surface was $185 per lineal foot, exclusive of the roadway.

The work was designed and carried out for the London County Council by their engineer-in-chief, Mr. Alexander R. Binnie, M. Inst. C.E., Sir Benjamin Baker, K.C.M.G., past president M. Inst. C.E., and the late Mr. J. H. Greathead, M. Inst. C. E., were consulted on several matters. The contractors were Messrs. S. Pearson & Son, whose representative and engineer on the work was Mr. E. W. Moir, M. Inst. C.E., who was responsible for the design of most of the special appliances used. The contractors had as chief assistants Mr. E. H. Tabor and Mr. G. H. Halden, Assoc. M.M. Inst. C.E., and Messrs. Everitt and Collingridge. The authors acted as joint resident engineers in charge of the work on behalf of the London County Council.

SMELTING FURNACE BURNING KEROSENE AS FUEL.

THE use of gas as fuel for smelting purposes is often rendered quite impossible by the distance separating the gas works from the furnace. The "Gold und Silber Scheideanstalt," of Frankfort on the Main, has constructed furnaces heated with kerosene, in which the oil is found to be a good substitute for gas, having quite as high a heating power.

The accompanying cut (Fig. 1) shows such a furnace, in which the greatest possible result is obtained with a very simple construction.

It will be seen on the diagram that the furnace is to be connected at F to a smoke flue providing a good draught. This involves no particular restriction in the choosing of the site for the furnace, as proper connections can be easily made in almost any locality.

Compressed air for the thorough combustion of the gases in the flame is provided by any suitable blower, and is admitted at x. It circulates under the burner, rising both on the inside and the outside thereof, and is driven into the flame, giving it a conical shape. In the annular burner there is an asbestos wick, D, which draws up the oil supplied from below through the pipe, S.

The flame is thrown against the bottom of the crucible, passes through the space between the crucible and inner shell, escapes by the opening at the top, and has to pass downward to get to the flue at F.

The circulation of the gases indicated by the arrows secures the most economical and complete use of the flame, and after as short a time as twenty minutes the temperature of the crucible is raised to 1,000° Centigrade, or to 1,300° in a very slightly longer time.

Our second cut shows a similar furnace, the compressed air being blown in centrally from the lower pipe, while the oil is delivered from the upper pipe to an annular chamber surrounding the wick. Here also the circulation of the flame is shown by arrows.

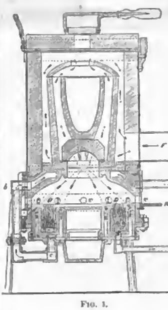

FIG. 1.

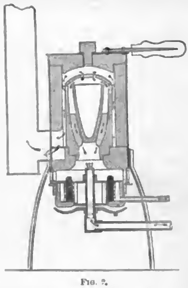

FIG. 2.

The first furnace will contain quantities up to 1,500 grammes of metal, while the second is constructed to hold as much as 20 kilogrammes. Any danger of explosion is absolutely avoided.

One of the most notable fleets of steamers hitherto constructed in the United States is designed for lake traffic—mostly iron ores—and bears the honored name of Sir Henry Bessemer. The vessels of the Bessemer fleet have been appropriately named after men famous for their connection with the mining, engineering, and metallurgical world. The flagship of the fleet is the Sir Henry Bessemer, while to the others have been given such names as Nasmyth, from the inventor of the steam hammer; Ericsson, from the builder of the Monitor; Corliss, the maker of engines; Krupp, Fulton, Watt, Siemens, Bell, Fairbairn, and Holley. Amid all the development of the lake marine and steel interests in the last few years it has strangely enough remained for this new company to honor the memories of the greatest men these industries have had by naming ships after them. These vessels were all built on a guarantee by the constructors of a capacity, on 14 feet draught, of 4,000 gross, or 4,480 net, tons. Each has slightly exceeded these figures. Were these vessels navigated on the draught of water for which they were built, they would be able to carry between 6,500 and 7,000 tons each, and they will be able to use nearly this depth of water this season, when the government's 21 foot channel between Duluth, Chicago and Buffalo will have been completed.—Iron and Coal Trades Review.

The Austrian government have placed a contract with Messrs. Yarrow & Company, of Poplar, for four first-class torpedo boats, of the improved Viper type. As the result of exhaustive experiments, the Austrian government have determined to fit the Yarrow boiler in the cruiser building at Pola, of 8,000 horse power. There will be eight boilers in all, having 2,500 ft. of heating surface each. These boilers, as well as the machinery for the vessel, will be constructed by the Stabilimento Tecnico, Trieste.

X RAYS AND PHOTOGRAPHIC COMPOUNDS: SOME RESEARCHES IN FLUORESCENT ACTION.

By V. E. Johnson, M.A.

It is a well known fact that when what have been termed the X rays fall upon certain chemical compounds they, by their stimulating action, cause them to emit a visible radiation to which the term fluorescence has been applied, the best known of such substances being sundry platino-cyanide salts, together with calcium tungstate and certain uranyl compounds—the best known because the most brilliant. The total number of bodies which fluoresce more or less under the stimulating action of the X rays is, however, very great, and increases, one might say, from day to day; so that it does not follow that that particular substance or compound which fluoresces with the maximum of brilliancy has as yet been discovered, although in the best screens undoubtedly a very large percentage of X ray energy is transformed, as is easily seen by placing two screens partly overlapping in contact, and observing the difference in illumination between the overlapping and non-overlapping parts, although this same difference may be due to another cause, as will be apparent later. It was not, however, with the intention of discovering, if possible, the most brilliant fluorescent substance, but rather, with the idea of gaining some knowledge with respect to the subject of fluorescence in general, that the following experiments, which led into many bypaths, were undertaken, the chemical compounds, etc., used in photography being chosen in preference as being ready to hand and of the greatest personal interest. It is to be hoped that the following brief account will be the means of inducing others who have not already done so to enter this fascinating field of research. The experiments were made with great care, in an absolutely dark room, with the Crookes tube (the ordinary focus pattern) completely incased in an opaque material, special measures being taken to completely screen off all light from the coil, such as that given off by the spark of the contact breaker, brush, discharge, etc. The spark used was a six inch one. The substances tried were in all cases, when necessary, ground to a powder in pestle and mortar, and dusted on to a piece of black cardboard through a fine sieve, no tacky substance, such as gum, collodion, etc., being used, nor was necessary, and was avoided by simply turning the tube round in such a fashion that the face of the platinum anode pointed upward instead of sideways or downward. Thus there was no waste of material. The pieces of cardboard dusted with the substance were held horizontally over the tube, and the chemicals returned to their respective bottles when done with. Much time and waste are obviated by this simple device, and possible errors arising from the presence of the tacky substance are avoided. The fluorescence in many cases was very faint, though not to be mistaken. A less powerful apparatus would probably give more negative and less positive results, and a more powerful one the opposite. Much, too, depends upon the physical nature of the body tried, but more of that anon. The substances tried with a negative result were the following: pyrogallic acid, alum (powdered), barium nitrate, collodion, lead acetate, mercury bichloride, caustic potash, sodium hyposulphite, glue, gum arabic, Epsom salts, potassium cyanide, potassium ferricyanide (solution), potassium ferrocyanide (solution), citric acid, sodium sulphite, sodium carbonate, tartaric acid, uric acid, borax, calcium sulphide (non-crystallized), uranium oxide, silver nitrate, chloride of silver, bromide of silver, and grape sugar.

The positive results were bromide of potassium, uranium nitrate, ammonium bromide, sodium acetate, sodium bicarbonate, chloride of sodium, mercury persulphate, chloride of gold, fluoride of potassium, hydroquinone, metol, amidol (very faint), potassium chloride, potassium citrate, potassium iodide, barium sulphide, fluoride of ammonium, calcium chloride. Potassium bromide was the most brilliant. The fact that the silver salts did not fluoresce led to an examination of the fluorescent action of glass. Glass of all kinds was found to fluoresce irrespective of shape, whether in the form of a plain sheet, a bottle, a prism, a lens, or a salt cellar of very irregular shape. That the shape made no difference was at once apparent, however, from the fact that the fluorescence was always and only on that side of the glass next to the Crookes tube. A bottle illustrated this very strikingly.

An ordinary photographic plate was found to fluoresce with sufficient distinctness to roughly make out the bones in ones hand. On removing the film from the glass the film still fluoresced, although not quite so brilliantly as the glass plate without the film.

The fact previously noticed, the non-fluorescence of the silver salts, led to an examination to discover the degree of fluorescence of gelatine and albumen. With respect to certain kinds both were found to be fluorescent. A piece of collodio-chloride printing paper (Paget) and a piece of unsensitized ordinary albumenized paper were found to be almost as brilliant as the photographic plate. A piece of bromide paper (Wellington & Ward's) showed no trace of fluorescence. Celluloid was found to be fluorescent, although not so brilliantly so as glass.

From these results it would appear that the fluorescence exhibited in the photographic plate is caused not (as has previously been supposed) by the fluorescence of the silver salts, but by the fluorescence of the substratum and support.

Various conclusions were drawn from these and many other experiments on this same mysterious and but little understood subject of fluorescence which may be here noted, as they may serve as a guide more or less to other future workers in the same field of research.

(1) The fluorescence of the substance is always on that side nearest the vacuum tube. This is well illustrated in the following cases: A glass bottle and a china saucer (the thicker portion on which the saucer stands appearing as a dark ring through the milky transparent whiteness of the whole). An unevenly dusted screen of some substance non-transparent to light, such as calcium tungstate, also exhibits this well—the thickly dusted portion appearing dark, the converted light rays from underneath (supposing the screen horizontal, fluorescent side uppermost) not being able to pierce the upper layers.

(2) An increase of fluorescent material is not necessarily an increase of brilliancy, but in time the reverse. A layer of non-crystallized calcium tungstate a quarter of an inch thick shows no fluorescence, a similar layer of uranium nitrate fluoresces well. A very thin layer of this same calcium tungstate fluoresces brilliantly.

(3) The substance should be in such a condition as to be as transparent to light as possible, and therefore (other reasons apart) a crystalline state is preferable.

For a good fluorescent screen it is also evident that the substance on which the fluorescent material is coated should be as transparent to the X rays as is possible, and that the coating of the screen should be as close as possible, so that no rays should pass through without filtration. If a tacky substance be employed, it would appear that it should possess as far as possible the characteristics of the fluorescent salt.

Among odds and ends that fluoresce under X ray stimulation may be mentioned powdered lump sugar, salt, and paraffin candles. Both transparent and opaque (to X ray radiation) substances fluoresce; many such could be quoted, but two of the most familiar are, perhaps, paste (chiefly lead glass opaque) and diamonds. Generally speaking, however, opaque bodies fluoresce the more brilliantly. It should be noted that glass is an amorphous body.

Genuine solutions of fluorescent substances (potassium bromide for example) are non-fluorescent. Chlorida of gold solution is, however, fluorescent; ordinary powdered sulphur non-fluorescent, but powdered roll sulphur fluorescent. Solutions must obviously be examined in a transparent non-fluorescent containing vessel.

As to whether the X rays exert any action of a primary character upon the silver salts seems much open to question; in any case it is of an extremely feeble character, and that we have in the silver salts the best sensitive recorder of X ray action seems most unlikely, although, of course, the unique power possessed by them of being so susceptible to rapid development when their altered molecules are but few in number is an advantage which could only be surpassed by some power of a like character possessed by another salt more susceptible to X ray energy.—Photography.

RECENT INFORMATION ON LIGHT ALLOYS.

Nickel-Tin-Aluminum Alloys.—These alloys are obtained by first melting pure aluminum, removing the dross and dirt from the surface, then putting in pure commercial nickel in thin sheets. The melting point of nickel is 1,500 deg. C., but under these conditions it is dissolved in the aluminum at 800 deg. to 900 deg. (bright red heat). The mixture is well stirred. When bluish sparks no longer appear on stirring, the tin is added. Three alloys are recommended, as follows:

	(1)	(2)	(3)
Aluminum	83	90	90
Nickel	2	3	4
Tin	15	10	10

The density of these alloys is 2·87 to 2·90. Alloy (2) is best for casting, as its shrinkage in sand is small. Alloy (3) is best for rolling, drawing or hammering.

Nickel-Iron-Aluminum.—These alloys are made in the same manner, melting 4 parts of nickel in 90 parts of aluminum and adding 1 or 2 parts of iron. The alloying requires, however, about 1,000 deg. C. to effect it. The alloy with 1 part of iron is very hard and very malleable; it rolls and may be forged; its elasticity is high, and it resists oxidation well.

Manganese-Copper-Zinc-Aluminum. — After a long series of experiments, De Susini is said to have found an alloy of these four elements which has very desirable qualities. The zinc, copper and manganese are first melted together in a plumbago crucible, and to make the final alloy the aluminum is melted and the necessary quantity of the first alloy added to it, keeping it at a red heat. Four mixtures are given, as follows:

Aluminum	97	95	92	90
Manganese	1·3	1·5	2·8	10
Copper	1·5	2·5	4·5	—
Zinc	0·5	1·0	1·5	—

Wolframinium.—This new alloy is due to Messrs. Reinhard and Isidore Roman. Its strength is quite high, showing a tensile strength when hard of 52,000 pounds, with 2 per cent. of elongation, and when annealed of 38,000 pounds, with 15 per cent. elongation. An analysis of the alloy has shown:

Aluminum	98·04
Antimony	1·44
Copper	0·37
Tin	0·10
Tungsten	0·04

Manganese or nickel may replace in it the copper, tin, or antimony. The metals are melted in the following order: Copper, tin, antimony, tungsten, aluminum, adding a small quantity of aluminum successively with each, in order to facilitate the melting. The Messrs. Lock, Lancaster, and W. & R. Johnson & Sons, of London, have acquired this alloy, and sell it in ingots, rods, etc. It casts easily in sand and moulds. Its color is white like silver. It resists reagents as well as pure aluminum, and has about the same specific gravity.

Partinium.—This is an alloy proposed by M. Partin, consisting of aluminum containing 4 to 10 per cent. of an alloy of copper, tin, arsenic, antimony and tungsten, or of an alloy of copper, tin, arsenic and aluminum.

Silicon-Aluminum.—Alloys of aluminum with up to 12 per cent. of silicon are strong and tough, but they deteriorate easily in the air or on contact with chemical agents, so that they cannot be used except well protected by paint or varnish.

Tin-Aluminum.—Alloys rich in tin, exposed to the air of a laboratory, become so brittle in a few days as to break of their own weight. They gain in weight by corrosion when left in water or even in the air. In water, the alloy with 15 per cent. of aluminum is most attacked. All these alloys are attacked by reagents more easily than either tin or aluminum alone.

Ferro-Silicon Aluminum.—Quite recently F. Krupp has found that an alloy containing 5 per cent. aluminum, 10 per cent. manganese, 10 per cent. silicon and 75 per cent. of iron is very suitable as an addition to molten steel. A simple alloy without manganese can also be used satisfactorily.—From L'Electrochimie.

SELECTED FORMULÆ.

To Shrink New Flannel.—New flannel should always be washed before it is made up. It can be cut out more accurately, and the grease extracted that it contains. Wash it in clean warm water, as warm as the hand can bear, and entirely by itself. Rub the soap to a lather in the water, or the flannel will become hard. Wash it in this manner through two warm waters, rinse it in another warm water, with just sufficient soap in it to give it a whitish appearance; to this water add a little indigo blue; wring and shake it well, and while drying shake, stretch and turn it several times. Flannel washed in this manner will be white and soft as long as it lasts. When dry let it be clapped and stretched with the hands, and rolled tight and smooth till wanted.

Cigar Flavoring.—

(1.) Macerate 2 ounces of cinnamon and 4 ounces of tonka beans, ground fine, in 1 quart of rum.

(2.) Moisten ordinary cigars with a strong tincture of cascarilla, to which a little gum benzoin and storax may be added. Some persons add a small quantity of camphor, or oil of cloves or cassia.

(3.) Tincture of valerian	4	drachms
Butyric aldehyde	4	"
Tincture vanilla	2	"
Nitrous ether	1	"
Alcohol	5	ounces
Water, enough to make	16	"

—Pharmaceutical Era.

Essences of Soap.—White Castile soap, 100 parts; alcohol, 80 per cent., 200 parts; pure carbonate of potash, 12 parts. The soap is dissolved in a wide mouthed bottle on the water bath by constant shaking with the alcohol, the carbonate of potash is then added. Then tint with saffron, or rosaniline and perfume. Leave for some days in the cold and filter. An excellent perfume for the above is obtained by mixing tincture of vanilla, 10; tincture of orris, 20; extract of rose, 20; extract of orange flowers, 50 parts. Bouquet recommends for the preparation of the essence: White soap, 1; alcohol, 85°, 3; distilled water, 1; and for medicinal purposes the following mixture, which lathers strongly in water: White Castile soap, 20; distilled water, 30; 90° alcohol, 60; potash, 1, and 1 per cent. of perfume.—Zeit. d. Allg. Œst. Apoth. Verein, x. 31.

Transferring Pictures, Prints, Etc.—In order to transfer prints of various kinds to glass, wood, etc., soak them for a short time in a solution of 10 parts of potassium hydrate in 90 parts of alcohol (more or less). This procedure is to soften the varnish in the printer's ink. After rinsing in pure water the print is placed face down on the plate which is receive the picture or print, covered with a dry sheet and then pressed with squeegee or in a letter press.

Colored prints are painted over with a colorless, sticky varnish, pressed against the object intended to receive them, and, when dry, the paper is removed by rubbing cautiously with an aqueous solution of potash.

Some years ago a French typographical journal gave the following curious process for the reproduction of any printed design whatever—pictures, printed pages, etc. The paper to receive the reproduction is treated with the following, which is applied with a sponge, or, preferably, with a soft, flat brush:

Gelatine	10	parts
Ferric chloride	22	"
Tartaric acid	10	"
Zinc sulphate	10	"
Distilled water	400	"

Mix in the dark, and keep in a deep, orange colored glass bottle (an ordinary bottle, tightly covered with a heavy, yellow colored paper, and kept in a close pasteboard box, will answer). The coating should be applied in a dark place, and the paper dried in the dark. When dry, place the design on the coated surface, and bring into close contact. Place on a sheet of glass, cover with another, clamp together, and expose to the direct rays of the sun until the yellow cover of the surface of the sensitive paper is bleached to a white. Remove from light, and develop by leaving for three or four minutes in the following:

Gallic acid	2	parts
Alcohol	7	"
Distilled water	100	"

If left exposed exactly the right length of time, the lines will appear on a white ground of an intensely black color. If exposed too long, they will become more or less gray.—Pharmaceutical Era.

Drying Sensitive Organic Substances.—To determine the moisture in soaps and other sensitive organic substances, C. C. Parsons (Jour. Am. Chem. Soc., Pharm. Jour.) uses an oil bath, putting the substance directly into a weighed quantity of hot oil, and weighing again after the moisture has been driven off. It is best to use neutral paraffin oil, without any admixture of animal or vegetable oils or fats, or mineral substances, and with specific gravity 0·920, flash test 437°, fire test 500°, and boiling point about 550°. The object of the high fire test is that the oil should be so freed from volatile matter that none of it will be carried off with the moisture in the substance to be dried. Ordinarily the whole operation may be completed in twenty minutes. It should be conducted in a drying closet kept at 240°. First, the oil is put into an evaporating dish and kept in the drying closet until it has the same temperature, then it is weighed and about one-sixth the quantity of the substance to be dried, weighed and added to it. If very moist, add in successive portions. The whole should be kept in the drying closet for a few minutes after effervescence has ceased. On again weighing, the loss indicates the amount of moisture driven off.—Pharmaceutical Era.

Mothol.—A pleasant deodorizer and moth preventive.

Alcohol	40	ounces
Tincture of capsicum	5	"
Naphthalene	1	"
Absolute phenol	1	"
Menthol	½	"
Oil of lemon grass	½	"

Mix and filter.

To be used in the form of a spray by means of an atomizer, where the moths frequent.—Chemist and Druggist.

ENGINEERING NOTES.

An interesting exhibit at the Tennessee Exposition is by the Sloss Iron and Steel Company, of Birmingham, Ala. It consists of a block of brown iron ore, 6 ft. high, 4 ft. wide, and 4 ft. long. It weighs about 5 tons, and is said to be the heaviest block ever mined in the State in one mass. It is stated that the company has a deposit of this ore 40 ft. in thickness at its mines near Leeds, Ala.

Sand tracks have been introduced into the gravity switching yard at Frederickstadt, Dresden, with a view to economizing labor, says Engineering. The trains here are marshaled by gravity, the grade provided being one per cent., which is sufficient to move the cars against the strongest east winds, but with a favorable wind the speed would be excessive were not means taken to check the speed of the cars. This has hitherto been done by brakes or by spragging the wheels. Recently, however, the sand track system has been adopted, the depth of sand over the rails being adapted to the atmospheric conditions prevailing day by day.

The compressed air workers have formed a union in New York. The longest time that the men say they can work in a day is eight hours, and that at a moderate depth. At great depth, where the atmospheric pressure is very great, they say they cannot work over three hours, with intervals of rest between. The schedule of prices and hours of labor as prepared by the union are as follows: From 55 to 70 feet depth, $2.75 for six hours' work; from 70 to 80 feet depth, $3 and four hours' work; from 80 to 90 feet depth, $3.25 and two hours' work; from 90 to 100 feet depth, $3.50 and one hour and twenty minutes' work. For overtime they will charge double rates.

Japan, according to a recent statement, had 2,950 miles of government and private railways at the end of 1896, while charters had been granted for 1,548 miles, and applications for charters represented 12,351 miles more, says the Railway Age. This shows a possible total of about 16,800 miles, which, if built, would give an average of 11¼ miles of railway to each 100 square miles of the entire kingdom, or considerably more than twice the present average for the United States. Projection is very different from construction, as we in this country know, but that nearly 14,000 miles of additional railway are even contemplated in the little empire of Japan, the estimated cost of which would be about $355,000,000, is suggestive of the great possibilities of the future. At the same time let no American railway man engage passage for Japan on the strength of these statements.

The work of track elevation in the city of Chicago is receiving more attention at present than for some time past. Besides the work of the Chicago & Northwestern and the Pittsburg, Fort Wayne & Chicago Railways, noted in Engineering News of May 20, the notorious Sixteenth Street crossing has just been ordered abolished by the city council. This work will require the elevation of the tracks of the St. Charles Air Line and four other railways and the depression of the tracks of the Chicago & Western Indiana and Atchison, Topeka & Santa Fe Railways, and will cost some $2,500,000. It is stated that the roads interested have signified their willingness to accept the ordinance and that the beginning of work may be expected at an early date. The character of the construction will resemble in a general way that of previous track elevation work in Chicago, which has been described in Engineering News of August 20, 1896, and numerous previous issues. The Sixteenth Street crossing has always been considered one of the most dangerous grade crossings in Chicago, and the prospect of its early removal is unusually gratifying.

The experimental tank which is to be constructed at Washington by the Navy department for trials with models of new ships will be the largest basin of its kind under cover in the world, says the Marine Review. Its dimensions will closely approach those of some of the largest dry docks, and the depth will be sufficient to float many of the smaller ships of the navy. On all sides it will be covered, and the water will be supplied by the city reservoirs or pumped from the Potomac River. From end to end the tank will be just 500 ft. long and 50 ft. across, and inside the water space will be 475 by 43 ft. Its depth will be 14 ft. Running across, close to the water, will be a carriage upon which there will be attached a dynamometer to register the resistance due to towing a model through the basin. Models varying in size from 10 to 20 ft., of every new ship to be built, will be attached to this machinery and drawn through the water. The wave motion will be observed and the resistance it offers will be calculated. The models will be plain affairs, constructed only with a view to presenting closely the actual lines of a ship it is proposed to build. Through the experiments it is estimated that the plans of all proposed vessels can be improved and valuable information gathered for use in designing the lines of ships. The cost of the tank will be $100,000.

The Southern Pacific Railway Company is preparing to adopt schedules of tonnage rating for its goods locomotives throughout the whole of its lines, the plan having been in use with satisfactory results on the Western Division for two or three months. According to the Railroad Gazette, experiments are now being made, and in order to secure uniformity on the widely separated divisions of the company—some in Texas and some in Oregon—the general manager has issued to the fifteen superintendents of the company a circular outlining the plan adopted on the Western Division. A train of loaded cars is made up, with a list showing the weight of one car, of the first two cars, the first three cars, etc., and this is supplemented by a list beginning at the rear end. Weights are shown in "M's" or units of 1,000 lb. This train is tested on a level or on an easy grade, with one of each class of locomotives in use on that division, and then with a locomotive of one class only, it is tested on the ruling grades. In these last tests an engine facing backward is attached to the rear end of the train, to attach and detach cars where necessary, to act as a helper where needed, and to act as the hauling engine where grades are tested both sides of summits. Tests are being made, both starting from a standstill and in the usual way, up grades at ordinary speeds.

ELECTRICAL NOTES.

An electric tramway has been projected for the Principality of Monaco, and has been definitely declared "of public utility" by a royal ordinance. The work has been intrusted to M. Henri Crovetto.

The new Huron Street lift bridge over the Milwaukee River at Milwaukee, Wis., is operated by a 24 horse power electric motor running at a normal speed of 450 revolutions per minute and geared to a train which operates the working struts.

The Electrical Review understands that the Rogers printing telegraph system is to have a thirty-day practical test on the lines of the New York Central Railroad between New York and Albany. This system prints the message directly at the receiving station.

The extent of the business of the Bell telephone companies is shown in the following extract from the American Bell Telephone Company's last annual report: "The companies operating under our licenses expended during the year $8,275,920.11 for new construction, to which amount is to be added an expenditure of $1,160,931.30 for land and buildings." This makes the round sum of over $9,400,000 expended in improvements in twelve months.

According to the Detroit Evening News, the extraordinary spectacle of a fountain of water springing from the top of an electric tramway pole has been witnessed in that city. It naturally drew a crowd who looked on with amazement. When a gang of men were set to work to discover the occasion of the phenomenon, in the course of time they came to a water pipe which ran beneath the pole. This had been eaten through with electrolysis, and the water burst through, entered the hollow iron trolley pole, and having nowhere else to go, came out at the top. Electrolysis trouble is usually ascribable to insufficient rail return. It is believed that such a pretty demonstration of the necessity of looking out also for bad work or accident in the insulation of the trolley line is unique.

Dr. Julius Precht, of Heidelberg, has, says Nature, just published an important thesis on cathode rays, Roentgen rays, and other radiations emanating from vacuum tubes, which confirms the view that these rays are of a highly complex nature. Besides the rays capable of being deflected by a magnet according to the law of Biot and Savart (which the author has verified by photography), Roentgen's, Goldstein's, and Lenard's rays are shown to be distinguishable by their chemical and photographic effects. Dr. Precht considers that a portion of the radiation from a discharge tube is not a wave motion, because the absorption of the rays in passing through paper varies with the time of duration of the radiation; it is suggested that this portion may be electric in its nature. Interference phenomena were obtained with direct and reflected Roentgen rays, and from these their wave length was found to range from 370×10^{-8} to 800×10^{-8} mm.; and observing that transverse light waves of this length cannot pass through black paper, the author seems to incline to the theory of longitudinal waves. By such interference experiments wave lengths were obtained nearly twice and four times as great as those found by Voller in observing the diffraction produced through a slit.

A system for lighting, heating, and ventilating railway cars by electricity has been given a practical test by the Pullman Company, and it has been highly commended. The mechanism of the apparatus is very simple. A plain gear wheel is attached to the car axle, connecting by ordinary cogs with the shaft of a one horse power dynamo which is securely placed on the car truck. By this means a constant and reliable electric current is generated, which is passed through a small storage battery, whereby the light is rendered brilliant and uniform, both while the train is running and when it is standing still. Each car is thus independently provided with its generating and illuminating apparatus, so that cars may be detached from through trains, when desirable, and sent over connecting roads without limitation. All the mechanism is securely placed beneath the floor of the car, completely incased to avoid dust and dirt. The apparatus weighs less than five hundred pounds, and is automatic in operation, thus requiring no personal attention, except at long intervals of time, when regularly inspected at terminal stations. The mechanism is plain, simple, strong and permanent in character, and not liable to suffer from friction or depreciation, and the many difficulties which have heretofore embarrassed the use of electricity for car lighting are wholly and effectually solved by its use.

Testing Alloys with Roentgen Rays.—The following new use for the X rays was indicated in a recent lecture in England by Mr. Heycock, as reported in The Electrician: "The lecturer," it says, "drew attention to the fact that the composition of metallic alloys is and always has been a vexed question, that is to say, it has always been very doubtful whether the metals which compose the alloys form a homogeneous mixture or whether they exist as small distinct particles which are capable of being separated from one another. Now, some metals, such as sodium, permit of the passage through them of Roentgen rays, while others, such as gold, prove to be quite opaque when submitted to the radiation from a Crookes tube. Having made an alloy of sodium and gold, containing a very small percentage of the latter metal, he allowed it to cool very slowly, just as the solution of potassium permanganate in water had cooled. When cold a very thin section was cut, which was then radiographed. The radiograph revealed the fact that the sodium had crystallized out from the general mass. This is one of the most interesting results which have been brought about by means of X rays, and it opens up a wide field of research in microscopic photography which will probably enlighten us considerably with regard to the true nature of alloys. The atomic weight of sodium is 23 and that of gold is 197, so that sodium is roughly eight times more transparent to X rays than gold. The atomic weight of carbon, on the other hand, is 12, and that of iron is 56, so their transparencies are only as 5 to 1. However, the difference is sufficiently large to warrant the X ray research into the true nature of the various brands of steel and iron."

MISCELLANEOUS NOTES.

The citizens of Dijon, France, recently voted a sum of money for putting a railing round a tree standing within the city limits. The tree bears a label which informs the sightseer that it is the oldest poplar in France. The town council has a record tracing the history of the tree since the year 722 A. D. It is 122 ft. in height and 45 ft. in circumference at the base.

Prof. Hilgard, of the California State University, says that the Australian salt bush can be grown successfully on arid and alkali lands; that it removes from the soil large quantities of sodium carbonate and sodium chloride, the two most injurious alkaline salts. In soils, therefore, where the percentage of alkali is near the danger point they may be sensibly relieved by planting salt bush for several seasons. The yield is nearly equal to that of alfalfa.

An exchange says that "almost within the Arctic circle, in north latitude 63 to 70 degrees, Iceland, with its population of 70,000, is warmed on the west coast by the Gulf stream, and can raise fair hay crops and sparse root crops. About 65 per cent. of the population are occupied in rearing sheep and cattle, which are largely consumed at home, the first named exported in moderate numbers to British ports. Sheep are not shorn, but in early summer the fleeces loosen on the animal, and the loose wool is easily detached; most of the surplus goes to England."

The Stockholm Industrial and Art Exhibition was, in accordance with the original programme, solemnly opened by the King of Sweden on Saturday, May 15. The King and Queen of Sweden, the Crown Prince and Crown Princess of Denmark, with their daughters, the Crown Prince of Sweden, who is the president of the exhibition, and his three brothers were present. The king made an eloquent speech, and the opening ceremony was on the whole most auspicious. We shall in due course comment upon this interesting exhibition, at which the Swedish iron and steel industries are most adequately represented.

The Philadelphia Ledger says: "The scheme for a ship canal from Lake Erie to Pittsburg is said to have been killed by the new Carnegie Railroad, built to carry Lake Superior ore to the Pittsburg furnaces; but if this is true, there never was much need of the canal. Mr. Carnegie, it is further said, has arranged to use 5,000,000 tons of ore this year, practically all of which, besides a large amount of miscellaneous freight in connection with it, will be carried over his railroad and will probably take up most of its carrying capacity. If the canal was to be of use only to feed the Pittsburg furnaces, that was very little reason for building it. If it was to take a large amount of lake commerce to the Ohio, and thence to the Mississippi and the Gulf, the new railroad will scarcely supersede it. The scheme, however, may well remain in abeyance a few years longer; in time the increasing call for water carriers for heavy freight will demand the building not only of this canal, but of several others, many of which are already projected."

According to London Engineering, the profitable utilization of the great masses of waste glass accumulated at factories is accomplished in a comparatively easy manner by M. Garchey, a Frenchman. He grinds the waste glass and puts the powder into a metallic mould, which is introduced into two furnaces in succession, in order to devitrify the mass; the first furnace serves for the gradual annealing of the mass, so that all the parts are devitrified as uniformly as possible; the mould remains about one hour in this furnace. Becoming soft, the molecules weld together and form a very consistent dough. In this condition the mould is taken out of the furnace and put into a second furnace that is heated to a very high temperature. In this furnace the mould is left for only a very few minutes, this second operation being intended to complete the devitrification and to make the mass more pliable. The substance is now in a condition to be pressed into different shapes, there being produced in this manner all kinds of ornamental or other building "stone," which is generally called ceramic stone.

Favorable notice is given in the columns of Machinery of the new artificial fuel known as egette or ovoid, in distinction from the more familiar briquettes for that purpose. Special regard has characterized the efforts put forth in this industry by Europeans to produce a fuel as cheap as possible and suited, in the highest degree, for convenient handling, storage and transportation. In America, however, much greater attention has been given to the thorough preparation of the coal, also to the quality of the pitch or binding material used, and to that size of blocks which insures the greatest economy in manufacture and moving. The systems of preparing the coal for coking and briquetting, by washing and jigging, originated in Europe, and have been there long practiced to such an extent that, almost throughout the whole of the Continent, coke can be guaranteed to contain only a certain per cent. of ash. The thorough washing or freeing from all slate or other impurities is, of course, one of the chief factors in determining the value of the product, since the utility of such fuel depends mainly on freedom from ash, or the amount of available combustible matter it contains.

Some interesting data relating to the estimated comparative local cost of different pavements in respect of first cost, maintenance, scavenging and watering over a period of thirty years have been furnished in a report by the borough engineer of Wolverhampton, England. Granite sets on a bed of Portland cement concrete, 6 in. thick, cost $3 per square yard, and have a probable life of thirty years. Australian hardwood blocks on a bed of cement concrete, 6 in. thick, cost $4.50 per square yard, and have a probable life of eighteen years, while creosote deal blocks similarly laid require the expenditure of only $3 per square yard, with a correspondingly diminished life of twelve years. Natural rock asphalt pavement, 2 in. in thickness, on a bed of Portland cement concrete 6 in. thick, can be laid for $3.35 per square yard, the life being calculated at fifteen years. The total cost of each of the above mentioned pavements during thirty years for maintenance, scavenging and watering is fixed as follows: Granite sets for an area of 7,992 square yards, $45,000; Australian hardwood, same area, $87,210; creosote deal, $73,900; and natural rock asphalt, $63,175.

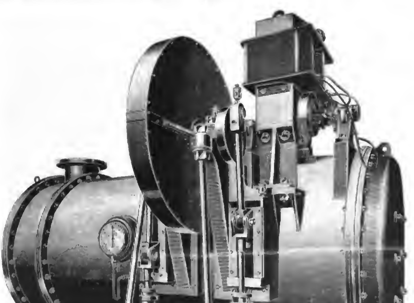
INDEPENDENT SURFACE CONDENSER.

In electric light stations the small auxiliary engines are a source of heavy additional expense and cost of working. The amount of steam used by them will vary from twice to six times the amount used per effective horse power when compared with large and more economical engines used for generating the electricity; moreover, these small engines will use nearly as much steam when the station is delivering only a small portion of its power as when it is working under its full night load. These small engines, moreover, owing to the smallness of their parts, often give considerable trouble in adjustment. To the air and circulating pumps illustrated below all these objections cannot be urged, for as they are electrically driven, the mechanical efficiency will be higher than that of the steam engines which are generally used to drive such pumps, and the power being received from the higher class engines of the station would be produced from them more cheaply than if independent engines were adopted.

The surface condenser illustrated is arranged with sufficient cooling surface to condense about 30,000 lb. of steam per hour, and is of the usual construction. The air pumps have been made self-contained with the condenser, the whole being bolted to brackets cast on the condenser body. The air pumps are driven by crank disks, with the pins placed on opposite centers, so that the weights of one pump will balance the weights of the other. The pumps are single acting, and produce a fairly even distribution of power. The air pumps are of the close top type, arranged to deliver their water at a higher level than themselves. On the shaft which carries these crank disks a heavy solid disk spur wheel is mounted, having machine cut teeth. This wheel receives its motion from the pinion mounted on the end of the motor shaft. The motor is a shunt wound machine, having a normal speed of 1,000 revolutions per minute, and receives its current from a 250 volt circuit. In order that the capacity of the air pump may be varied to suit the load on the station, resistances have been provided, so that the speed can be reduced in six stages to 375 revolutions per minute.

The centrifugal pumps illustrated below have 9 inch deliveries, and each is capable of delivering about 12,500 gallons per minute. As will be noticed, these pumps are driven from the opposite ends of the motor shaft, one pump being driven by a flexible coupling and the other by a friction coupling. During the day, and when the load on the station is light, it is intended that one pump only should be used, and as the load on the station increases the other pump is put in motion by means of the friction clutch. As the length of pipes in the station for which these pumps have been made is fairly long, to make the capacity of the two pumps twice that of the one it has been found necessary to compound wind the motor in such a way that when the second pump is started the speed will be slightly accelerated. The compound winding also possesses another advantage—that in case an attendant should too suddenly throw the clutch into gear, causing a heavy strain to be momentarily put on to the motor, while increasing the velocity of the water in the pipes, the motor would lag, gradually coming back to its intended speed as it was able to put the water into motion. The normal speed of these pumps is about 420 revolutions, and they also are arranged to work on a 250 volt circuit. The condenser, air and circulating pumps, and motor have been constructed for the Bradford Corporation New Electricity Works, under the supervision of Mr. A. H. Gibbings, the borough electrical engineer.—Engineer.

THE BUSHBURY ELECTRIC DOG CART.



INDEPENDENT SURFACE CONDENSER.

THE ENGINEER MOTOR CAR COMPETITION AT THE CRYSTAL PALACE, LONDON.

Everyone who is interested in the development of the horseless carriage or motor car—and who is not—will be greatly disappointed that the generous and laudable attempt of The Engineer, of London, to stimulate the youthful industry by the offer of an eleven hundred guinea prize for the best motor car should have ended in an inglorious failure. The competition was first suggested by our contemporary about two years ago, and shortly afterward the scope of the competition, its aims, and the conditions governing the exhibitors were published in full. It was announced that prizes would be awarded for the encouragement of manufacturers and designers of horseless carriages.

The objects of the competition were stated to be strictly utilitarian, The Engineer believing that an important trade might be created in this class of machinery, and that the removal of the restrictions on the use of mechanically propelled vehicles would result in great benefit to the farmers.

The date of the trial was originally fixed for October, 1896. As the time approached, it was found that the motor cars which were to enter the competition could not be completed in time, and a postponement was made to June, 1897. Seventy-two entries in all were received, and as the day drew near there was another request for a postponement, the period of delay asked for varying between one month and a year. This The Engineer did not grant; and when the judges, Sir F. Bramwell, Mr. Aspinall, and Dr Hopkinson, appeared on the scene at the appointed hour, there were only seven out of the seventy-two applicants on the ground, and of these only five were ready to take part in the contest.

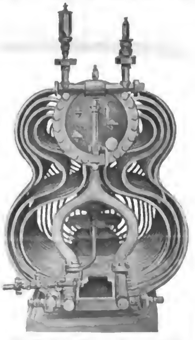
Our contemporary has this to say in the course of a pessimistic editorial:

"The end of it all is very dissatisfying and disheartening; only five vehicles appeared at the last for the competition, and 'the judges have decided that they cannot award a prize to any of the cars exhibited. It will therefore not be necessary for the trial run to Birmingham to take place. Although the judges cannot see their way to award any prizes, the steam car of the Liquid Fuel Engineering Company, and the Bushbury electric car of the Electric Construction Company, are highly commended.' This adverse decision, yet more unsatisfactory to us than to the competitors, was only arrived at after a most painstaking and exhaustive investigation by the judges. On Friday Mr. Aspinall spent some hours at the Crystal Palace examining the cars. On Monday Mr. Aspinall, first, then Dr. Hopkinson, and finally, Sir F. Bramwell, examined and tested the cars in the Palace grounds. Their verdict was only pronounced late in the evening after mature deliberation, and we venture to say none of the competitors will feel disposed to quarrel with the soundness of the decision, however much they may regret it.

"One result of our essay has been satisfactory. It has cleared the air. It has placed the world in possession of facts concerning the motor car industry in this country. There is at present no such industry. There is no such thing as a thoroughly satisfactory self-propelled vehicle. If a motor car of the kind existed, it would have been submitted for competition. We have received dozens of applications to postpone the trial. The period of delay asked for varied between one month and one year. It will be remembered that several months have elapsed since the world was assured that the construction of motor cars was a flourishing industry. Already we had put off the date of trial from October, 1896, to June, 1897. We have to deal with things as we find them. We have every reason to believe that the best that England can do at present was shown at the Crystal Palace on Monday; and, in the opinion of three most competent engineers, the carriages shown were so imperfect, so unsuitable to the fulfillment of the purposes which a motor car ought to serve, that they would not submit them to further trial. Administering the funds placed at their disposal to award as prizes, the judges have held that none of the vehicles so nearly satisfied the conditions with which a self-propelled motor car must comply that it was entitled to the final and crucial test of a long run. As we interpret this decision, it means that even if any of the cars had run to Birmingham and back within the prescribed period, that fact alone would not have compensated for its defects."

Although The Engineer is undoubtedly right in con-

cluding that, according to its own standard of what goes to make a successful motor car, there is no motor car industry in England, the statement is only true when taken in this limited sense. For it must be remembered that all vehicles propelled by light oil or petroleum spirit were at first rightly excluded from the competition. It is true that subsequently an offer was made of a five hundred dollar prize for vehicles using light oil; but, in view of the hostile attitude which has

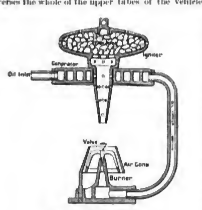


MOTOR CAR BOILER, LIQUID FUEL ENGINEERING COMPANY.

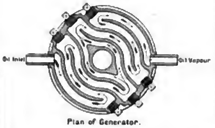
characterized The Engineer in reference to such motors, it is not surprising that they failed to put in an appearance at the trial.

We reproduce from our contemporary the accompanying illustrations and details of competing cars. The five vehicles included a four seat petro-car and a petro-cycle, sent by Messrs. Roots & Venables; a steam van by the Liquid Fuel Engineering Company, of the Isle of Wight; the Bushbury electric cart by the Electric Construction Company, of Wolverhampton; a light oil car by Mr. Cornell, and a car by the Yeovil Motor Car and Cycle Company.

The Roots & Venables cars, classes A, B, and D, represent most praiseworthy attempts to construct heavy oil engine motor cars. The first is thus described: The motor, which is twin cylinder, is of 3·2 brake horse power and runs at about 510 revolutions per minute. A silent running chain connects the crank shaft to a countershaft on which are keyed the friction clutches. These clutches drive either of two chain wheels, which are connected by chains and chain wheels directly to the axle. The cranks of the motor are placed opposite each other, so that one piston and crank balances the other, which it effectually does. The inventors' method of governing, by operating the exhaust valve and the oil feeder simultaneously and by the same mechanism, enables them, they say, "to obtain a clean exhaust, and the construction of parts surrounding the vaporizer and igniter relatively to one another insures complete combustion." The method of governing was only arrived at after many years of experiment. Their automatic burner for heating the ignition tube enables the motor to run continuously as long as it is supplied with oil, without any attention whatever, which they think cannot be claimed for any other oil motor, whether for vehicles or other purposes. The water is pumped through the jacket; it then traverses the whole of the upper tubes of the vehicle



SECTION OF BURNER



Plan of Generator.

frame and then by half the lower tube to the water tank, thence by the other side of the lower tube of the frame back to the pump. This enables a much less quantity of water to be carried.

There is only one countershaft, which not only drives the main axle directly, but also operates the valves and carries the governor. The inventors say that they have found by experiment that it is advisable to have the driving countershaft directly over the axle rather than placed horizontally with it, and to have an intermediate stiff spring for various reasons, three of which are as follows: (1) In meeting with a large obstacle, such as a brick, the driving wheel, if the car is going at a slow speed with but little momentum, is suddenly checked, and the chain may snap or shear a tooth off the wheel; in this car the chain slackens to reduce the jar; (2) slack in the chain is easily taken up, and the chain can always be kept tight; (3) the chain runs more smoothly, and the power is conveyed through the clutches more evenly and steadily, with less "grips and slips." The steering of the car can be done at full or slow speed with the finger and thumb, and is always positive. No gear wheels are used anywhere in the motor or car, all driving is done by chains to obtain silence.

The Roots petro-cycle carries two persons, the rear one steering and driving. There are three wheels, two in front and one, the driver, at the back. The wheels are fitted with solid rubber tires. A cross bar, connected by links to the two front wheel heads, steers both wheels at the same time. The motor is of $1\frac{1}{2}$ brake horse power and runs at about 510 revolutions per minute. A silent running chain connects the crank shaft to a countershaft, which is connected by a chain to a second countershaft, on which is fitted a friction clutch. This clutch drives either of two chain wheels, which drive the spindle of the back wheel by chains. The water tank is placed on one side of the frame to balance the fly wheel on the other. The cooling water is conveyed from the tank through the tubular frame of the car and passes through a coil of pipe surrounding the fly wheel, and is thus cooled by the air given off at the periphery by rotation. The ignition tube is first heated by a separate lamp, which is removed or extinguished as soon as the engine is started. The tube is afterward kept hot by means of an automatic burner. The attention of the judges was especially drawn to: 1, The tubular frame for conveying and cooling the jacket water; 2, the coil round the fly wheel for cooling the jacket water; 3, the automatic burner; 4, balancing the fly wheel by the water tank; 5, making the same governor govern both the oil feed and the exhaust valve; 6, doing without the use of gear wheels at all, either in the car or motor; 7, the construction of the ignition tube relatively to the port and combustion space, enabling a complete combustion to be obtained. It would be quite impossible to make the special features of these cars intelligible without drawings, which, for the reasons we have given, we do not publish.

The Yeovil motor car, class B, is a light business carriage for two persons. It is driven by a two-cylinder Petter patent petroleum engine, working on the Otto cycle and using ordinary petroleum, such as the American brand of "Royal Daylight." The cylinders are arranged side by side and fire alternately. The explosions are effected by means of two ignition tubes heated by a single blow lamp. The air inlet valves of the motor are operated by the suction of the piston, the exhaust valves by means of levers driven by chain gearing from the crank shaft. The motion is taken from the crank shaft to an intermediate shaft by means of sprocket wheels and chains, reducing the speed in the ratio of 2·8 to 1. A friction disk on the intermediate shaft is made to grip the chain wheel by lateral pressure applied to the end of the shaft by a hand lever. The intermediate shaft drives on to the rear axle by either one of two chains, the one gearing in a ratio of 12 to 32 and the other of 6 to 36, providing fast and slow speeds of ten and four miles respectively. A square clutch on the intermediate shaft between these two chains throws either one of them into action. The rear axle drives only one of the rear wheels of the carriage. The patent reversing motion is taken from the crank shaft by a belt. This belt drives a loose pulley carried on a foot lever. When reversing, the friction clutch for forward driving is released, the foot lever is held down and the back of the belt pressed on to a pulley fixed on the intermediate shaft. A brake is held on the fly wheel by a spring to control the engine when the carriage is at rest. When the carriage is in motion this brake is held off by a hand lever. Two pairs of ordinary carriage brakes are applied to the rear wheels, and the reversing motions provide a strong additional brake in case of emergency.

The Electric Construction Company's dog cart, class B, is designed to carry two persons seated side by side. The motive power is derived from accumulators, and the motor is at rest when the car is standing. It can travel up to 12 miles an hour on a good level macadamized road, and has surmounted gradients of 1 in 14 at a walking pace. It is not claimed that the accumulators will carry it under average conditions more than twenty miles without recharging. It can be made to travel backward at a walking pace. Its weight is about $13\frac{1}{2}$ cwt., exclusive of passengers. There are two driving wheels, and one steering wheel in front. The two pole motor is geared by means of a Renold chain to the driving axle. The driving wheels are keyed to the axle, which is divided into two parts, united midway between the wheels by an ordinary bevel wheel differential gear, to the case of which the sprocket wheel is attached. The steering wheel is mounted in a fork, and the backbone is pivoted on it by a joint having universal motion. Diagonal side braces are attached by joints to the lower extremities of the fork, and at their other ends to the front of the cart; these keep the fork in position, and permit of the wheel locking; they also cause the wheel when locked to be deflected from the perpendicular toward the side of the greater circle described, thus greatly adding to the stability when turning.

The steering wheel is guided by leather reins, running through eyes in a cross bar attached to the top of the fork. A bolt is provided, by which the wheel is kept in mid position; this is released automatically when tension is applied to the reins. The switch gear consists of a reversing and a controlling switch, placed under the driver's seat; the former is manipulated by a vertical lever on his right hand, the latter has four positions: (1) Off; (2) two parallels of twenty cells in series, in circuit with the motor; (3) forty cells in series, in circuit with the motor; (4) forty cells in series, in circuit with the motor, with a resistance in parallel with the magnets. The controlling switch is a roller actuated by the driver sliding his seat forward when starting or accelerating the motion, and sliding it backward when slackening the speed or cutting off the current. When the controlling switch is in the first position and the car is running, if the reversing switch be set to backward, the motor is closed on itself in circuit with a resistance and generates current. This combination is chiefly of use in checking the speed of the cart on long descents. For bringing the cart to a stand, a band, actuated by the foot, is applied to a cast iron drum on the motor axle.

The motor is carried by a frame, articulated at one end to the road axle bearing cases and at the other end slung by an elastic attachment to the under side of the foot board. In working, the distance between the motor and road axles is fixed, but it can be adjusted to compensate for wear in the chain. The driving wheels are 39 in. diameter and the steering wheel 45 in.; they are of steel throughout, with solid rubber tires. All three wheels are fitted with ball bearings. The sprocket wheel is $20\frac{1}{2}$ in. diameter; the chain is $\frac{5}{8}$ in. pitch and has a breaking strain of over 600 lb. About

ROOTS & VENABLES PETRO-CAR.

three-fourths of the weight is carried on ordinary elliptical carriage springs, resting on the bearings of the driving axle, the rest of the weight is carried by the front wheel. The gage is 4 ft. 6 in. and wheel base 5 ft. 6 in. All the working parts are boxed in, but are easily accessible from above. The motor bearings receive continuous lubrication from an endless chain dipping into a reservoir of oil. The motor is series wound and has a slotted armature, drum wound, with Eickemeyer coils, and carbon brushes are used. The magnet is two pole, wound with a single coil of square wire. The commercial efficiency is about 80 per cent., with 80 volts 10 amperes, at 700 revolutions per minute, this output approximately corresponding to a speed of ten miles an hour.

The accumulators are of the Faure-King type, manufactured by the Electrical Power Storage Company, Limited. There are four boxes, each containing ten cells, the total weight being about 5 cwt. Each cell consists of two half plate negatives and one positive. The rated capacity is 40 ampere hours at a discharge rate of 5 amperes, or about 28 ampere hours at a discharge rate of 15 amperes. The accumulators are carried in the body of the car, and terminals are provided for charging them in place, for which current at 100 volts is required. They are completely discharged when the volts drop to 74, and then require about seven hours to recharge. The depth of the boxes and cells is such that violent jolting does not cause the acid to be spilt.

By far the most interesting vehicle shown was the Liquid Fuel Company's van, class C. This company has been engaged for some time in the construction of launches and small yachts, some of these indicating about 200 horse power. Steam is generated in a water tube boiler, the fuel used being petroleum. The application of this boiler and furnace to road locomotion is a new departure on the part of the firm.

About two-thirds of the length of the van inside are available for passengers or goods. Under the floor are placed a pair of horizontal tandem compound engines. These are so small that they resemble models. They are beautifully made, and running at 625 revolutions per minute, with a pressure of 250 lb. they give about 12 brake horse power. The crank shaft is geared about 2 to 1 to a countershaft, which is geared about 4 to 1 on the road wheels. Thus the carriage wheels make one revolution for about 8¼ revolutions of the crank shaft. Under the driver's seat, which extends across the front of the van, is a box, the seat forming the lid. In the box are two horizontal plunger feed pumps, driven by an inclined shaft and bevel gear from the first countershaft. One of these pumps is spare. There is, besides, in the box a little horizontal double acting steam donkey pump, for feeding the boiler when the van is standing. The driving wheels are turned round by toothed wheels of good size secured to the wood spokes. These wheels are inclosed in cases, so made that it is claimed that no dirt can get in. The engine, and all the gearing, indeed every portion of the mechanism, is readily accessible, all the arrangements having been carefully studied and worked out on lines which commend themselves at once to the professional eye.

Steam is generated in a tubulous boiler, a sectional view of which is given in the accompanying engraving. The drawing explains itself to any one who has ever seen a water tube boiler of the Thornycroft or Normand type. The tubes of solid drawn copper are not rolled in, but are fixed by a patented screwed joint. The ends of the tubes are flanged after running nuts have been put on them, and these nuts are then used to force home the tube ends, copper to copper, and to make a joint; the boiler stands across the car, just behind the front seat. The water tanks serve as two longitudinal seats in the van. The steam drum is of Elmore deposited copper, and any tube may be taken out and replaced in a very short time. The arrangement for burning the petroleum is very ingenious and highly satisfactory, and will, we think, be readily understood from the accompanying engravings. The oil is delivered into a "gaseller" over the flame, which serves to spread the flames and hot air. The oil is driven into this gaseller by the pressure of air maintained over its surface in the tank by a small pump worked by a handle at the driver's right hand. The petroleum vapor thus produced passes down through a pipe as shown to a conical burner, and the amount which issues is regulated by a tapered pin, the position of which is controlled automatically by the boiler pressure. The combustion produced is very complete, and the boiler made at all times as much steam as the engines could use.

LIGHTING AMERICAN CITIES.

THE cost of street lighting in New York City for the year 1897 will be in excess of $1,250,000. The specific appropriation for this item is $1,222,821, to which are to be added sundries, which will probably bring it up to the total named, says the New York Sun. Philadelphia spends even more than does the city of New York in a year for lighting its streets and alleyways, the total expense being $420,000 for gas and $947,000 this year for electricity. These items collectively do not foot up to so much as New York pays, but while New York gets its supply of gas from seven different companies, and its electricity for lighting from ten different companies, Philadelphia owns its own gas plant, and since 1855 has had entire control of it. To the money actually disbursed for gas, therefore, must be added in the case of Philadelphia a reasonable interest upon the original investment, and some account must be made of the public property used for the works.

Chicago expends in a year $125,000 for gas lamps which illumine with indistinctness some of her streets, the major portion of which are unpaved roads separated from the buildings which front them by wooden sidewalks resting in the mud. Boston is an American city which, in proportion to its population and area, makes generous provision for public illumination. Boston spends in a year $290,000 for gas and $270,000 for electric lighting, a total of $560,000, the extent of which may be best understood by comparison with the expenditures for the like purpose in Baltimore, a city of the same population, practically, and of about the same area. Baltimore spends in a year $220,000 for gas and $140,000 for electric current. Cincinnati spends in a year $200,000 for gas and $75,000 for electric lighting. The area of Cincinnati is about the same as that of Boston, and about one-half of the present area of New York, Wakefield and the Bronx Valley villages included. It is a fact, not known to some of the most zealous and ardent of the Good Government Club reformers, that the annexed villages on the Bronx are lighted with neither gas nor electricity, but with naphtha lamps. These lamps are not expensive; neither is the naphtha used in them, but the distance between lamps is such that the traveling expenses or mileage of those intrusted with the task of communicating flame to the wicks is a considerable item of expense.

San Francisco expends in a year $300,000 for public illumination, both gas and electricity, and St. Louis a like amount. In Pittsburg the advantages of natural gas have been utilized of late years, and the expense for public illumination is $250,000. In Brooklyn it is $520,000—$160,000 for gas and $360,000 for electric current. Washington, the local affairs of which are under control of the Federal government and subject to acts of Congress, spends in a year for electric lighting $175,000. St. Paul, Minn., expends as much, and New Orleans, $225,000. Two American cities which show a distinct partiality for electricity as a means of public illumination are Denver and Detroit, and there are, practically, no cities which have not utilized, to some extent, the benefits of electricity. Buffalo expends in a year $300,000 for purposes of illumination, and as the area of the city is small, it should be one of the best lighted of American cities.

THE PREVENTION AND REMOVAL OF SMELLS.*

By FREDERICK R. GREEN, Ph.G., Muscatine, Iowa.

PREVENTION of Decay.—Evil odors are equally penetrating with sweet smells. They diffuse themselves through the air and affect the senses unpleasantly, even when the absolute quantity of matter present is too minute to be detected by our most refined methods of chemical analysis. Unlike the sweet odors, however, they are produced everywhere around us, and are, therefore, a universal source of more or less perceptible irritation and annoyance. To prevent the introduction of evil smelling substances into the atmosphere which surrounds us, and, when present, to remove them, has consequently been at all times an object of desire. The attainment of this desire has been rendered both more easy and more perfect by the discoveries of modern chemistry.

The smells which usually arise from the decomposition or decay of the bodies and droppings of animals can often be either arrested or altogether prevented. Extreme cold, for example, such as is sufficient to freeze and harden the dead body of an animal, will preserve it in a state of absolute freshness, even for thousands of years. In northern climates the freezing of flesh and fish is the common way of preserving it; and in the ice cliffs on the banks of a Siberian river the entire body of an extinct species of elephant has been met with, so little decayed as to be still greedily devoured by dogs. Even moderate cold, if accompanied by a dry wind, will prevent decomposition, the former retarding the decay till the latter removes the moisture which is necessary to its continuance. The cargoes of fresh meat brought from distant countries are kept unchanged by means of cold. The heat in the meat chambers of such a vessel is withdrawn by means of the evaporation of very volatile liquids, such as condensed sulphurous acid gas, ether, or liquid ammonia. These liquids in being vaporized absorb heat and so produce cold. Or the total exclusion of air will have the same effect, as is seen in the tinned meats, now so useful, not only in long voyages and in remote parts of the earth, but for bringing cheap and excellent supplies of animal food to our shores.

Decay can also be prevented by the direct application of chemical substances. This is done when fresh meat is immersed in sugar, or when it is impregnated with common salt or with a mixture of common salt and saltpeter. These substances fill the pores of the flesh and thus preserve it by excluding the air. And they withdraw the moisture of the flesh and render the latter less favorable to the development of those minute organisms, both animal and vegetable, which incite and increase decay. Volatile tarry matters, such as creosote and carbolic acid, which are contained in the smoke from peat and coal, in wood vinegar and in the spirit which is distilled from coal or wood tars, act in a similar way. They combine with the fiber of flesh or fish and retard its decay, until the removal of moisture by evaporation renders decay both slow and difficult. It is in this way that the smoking of fish or flesh contributes to a speedy cure, saving both time and salt, rendering the cure more certain and adding at the same time an artificial flavor which to many is very grateful.

Charcoal, when recently burnt, has much efficacy in preventing the offensiveness of animal decay from becoming sensible to the smell. Sprinkled in the state of powder over the parts of dead animals, it preserves them sweet for a length of time. Placed in pieces beneath the wings of a fowl, it keeps away much longer than usual any appearance of taint. Or, if strewn over substances already tainted, or mixed with liquids which have acquired the unpleasant smell of decaying organic matter, it removes the evil odor and makes them sweet again.

The Disguising of Smells.—Where evil smelling decay of any kind commences, or where volatile substances which disagreeably affect the organ of smell escape into the air from any source, we naturally desire to rid ourselves of the unpleasant sensation. This we generally wish, and always ought, if possible, to do by removing the substance to which the noisome smell is owing. In the great majority of cases, however, we merely overpower or disguise it. We are content to mingle with the smell we dislike some odor we can enjoy, and to leave floating in the air around us the evil and the good together, to produce unheeded their natural effects upon the system.

Sweet odors are thus the natural disguisers of evil smells. They are the only resource of rude and dirty times against offensive emanations from decaying animal and vegetable substances, from undrained and untidy dwellings, from unclean clothes, from ill washed skins and from ill washed stomachs. The scented handkerchief in these circumstances takes the place of the sponge and the shower bath; the pastile hides the want of ventilation; the attar of roses seems to render the scavenger unnecessary; and a sprinkling of musk sets all other stinks and smells at defiance. The "sixty stinks of Cologne" may thus be at once the parent and grand consumer of its artificial rivers of scented water. The fiercest demand for the luxury of civilized perfumes may exist where the disregard for healthy cleanliness is the greatest. Even the burning of incense at the altar may find a merely rational use in disguising the dank and unwholesome smells which damp walls and floors engender, and in hiding from the senses of the worshiper the noxious effluvia which slowly decaying bodies in hidden vaults are continually giving off.

The Removal of Smells.—The absolute removal from the air—at least from a limited portion of it—is not a difficult task. The substances by which this is effected are known in modern sanitary language by the name of deodorizers.

Of these deodorizers, or smell removers, charcoal in its various forms is one of the cheapest, most abundant and most efficacious. Mixed with fermenting night soil or with the contents of our common sewers, it sweetens them almost immediately, and it produces a like effect upon almost every variety of decaying animal and vegetable matter. Spread to the depth of two or three inches over a festering graveyard, or even over a decaying dead body, it is said to prevent any evil odors from rising into the air or becoming sensible to the smell.

Animal charcoal, such as is produced by the charring of animal substances out of contact with the air; peat charcoal, seaweed charcoal, and the black powder produced by charring together a mixture of earth and vegetable matter, are more efficient in the removal of smells than common wood charcoal, however finely it may be powdered. It is this power of absorbing evil odors which strongly recommends the different kinds of charcoal to the sanitarian for removing the smells of graveyards, cesspools, drains and other places where filth has been permitted to accumulate.

This remarkable action of charcoal is due to three properties: First, its remarkable porosity. In consequence of this it absorbs gaseous substances in large quantity and condenses them in its pores. Second, the special affinity which charcoal exhibits for certain strong smelling and coal burning substances. So powerful is this affinity that if a tablespoonful of finely powdered animal charcoal, or twice as much newly burned wood charcoal, be shaken up with a pint of stinking ditch water and the mixture filtered, the water will pass through bright, clear, and with little of either taste or smell. Third, the oxidizing influence it appears to exercise upon the substances it absorbs. Many of these substances, whether gaseous or solid, whether strongly smelling or strongly coloring, as soon as they are laid hold of by the charcoal, begin to unite with oxygen, to lose their characteristic properties and to change into new chemical compounds.

Peat, if dry and in powder, acts also as an absorber of smells. It is likewise of an acid nature, which enables it to combine with and thus retain ammonia and many of the stinking substances it has absorbed. Earth rich in vegetable matter acts in a similar manner, and even some varieties of clay purify the water that filters through them. The porous matter obtained by burning together clay and vegetable matter under cover has powerful absorbing properties.

The Destruction of Smells.—Substances that absorb and remove evil smelling bodies do not necessarily destroy their smells or take away any poisonous quality they may possess. Thus water absorbs sulphureted hydrogen, but acquires, at the same time, its offensive smell and its poisonous property. Heat the impregnated water, and the gas escapes again into the air with all its original qualities. Bodies which act as water does in this case remove but do not change the smelling substances. But, if into water or air which smells of sulphureted hydrogen a little chlorin gas be introduced, the smell of rotten eggs will disappear almost instantaneously. The sulphureted hydrogen is decomposed and destroyed. It no longer exists, and consequently both its smell and poisonous influences are gone. Water, as regards sulphureted hydrogen, is a smell remover or deodorizer. Chlorin acts upon the same substance as a smell and poison destroyer or disinfectant.

This distinction is not without its practical importance. Water, soil and other absorbents may remove and retain noxious substances, so long as cold or wet weather continues, but let heat and drouth return, and forthwith from water and soil they steam up again more or less unchanged. Hence those reeking miasms which spread mortal fever and chattering ague over entire provinces.* The disinfectant decomposes and destroys the evil compound, so that no change of circumstances can bring it into activity again.

All disinfectants act chemically. They either decompose or they combine with the noxious substances and produce new compounds which, if not always void of smell, are comparatively harmless in their action upon the human body.

Nitric oxid gas is produced when nitric acid is poured over pieces of copper in a glass or earthenware vessel. As it rises into the air it combines with oxygen and water, and forms red fumes of a strongly acid nature, which diffuse themselves through the atmosphere. These fumes have a somewhat uncertain action upon the noxious substances, contaminating the air; moreover, they provoke cough, and cannot be breathed with safety, and they corrode nearly all metallic substances with which they come in contact.

Sulphurous acid gas is produced when sulphur is burned in the air. It is one of the offensive substances classed with mineral smells. In large quantity it is both noxious and offensive to breathe, but as a disinfectant it may often be used with advantage. Hence the very common practice of fumigating with burning sulphur, a sulphur pastille being one of the best and neatest forms of using this substance. The first effect of this gas when diffused through the air is to overpower all smells and thus to make them imperceptible;

* Western Druggist.

* The noxious paludal effluvia commonly are thought to be microbic, and not gaseous.—Ed. W. D.

it acts as a smell disguiser. Its next effect is chemically to decompose or destroy such offensive substances as the sulphureted and phosphureted hydrogens that pervade nature.

Hydrochloric acid gas is produced when sulphuric acid is poured upon common salt. It unites with the moisture of the air the moment it is disengaged, and forms white, strongly acid fumes, which provoke cough and cannot be breathed. These acid vapors will act upon and destroy many kinds of strong smelling and noxious gases and vapors which may be present in the air.

Chlorin gas is obtained when hydrochloric acid is poured upon finely powdered black oxid of manganese; or when this powdered oxid is mixed with the common salt before pouring sulphuric acid upon it, as in the preparation of hydrochloric acid gas above described. Chlorin is a heavy, greenish colored, suffocating and strongly smelling gas. It decomposes sulphureted hydrogen, phosphureted hydrogen, ammonia, and nearly all other gaseous compounds and evil smelling vapors which escape from decomposing vegetable and animal matter. It acts upon all organic substances almost without exception.

Chlorin has long been employed as a remover and destroyer of unpleasant smells. It is the most generally efficient for this purpose of any gaseous substance with which we are acquainted. It is further recommended by being easily and cheaply prepared and by producing its good effects even when so much diluted with the air as to be inhaled without injurious effects. It can thus be used within a building without displacing its occupants and with little inconvenience even in the chambers of delicate invalids.

Chlorid of lime possesses the chemical qualities of an efficient disinfectant in a high degree. It consists of lime and chlorin; of these the lime combines with acid bodies, while the chlorin either combines with or decomposes the alkali compounds represented by ammonia. And at the same time it possesses a remarkable power of oxidation; it burns up many of the offensive neutral bodies evoked during decay. It exerts this influence even upon sulphureted hydrogen. Spread in the solid form upon any fermenting mass, it destroys the noxious bodies as they are formed. Dissolved in water and sprinkled over bad smelling chambers, or mixed with more or less fluid collections of putrid matter, it brings sweetness everywhere.

THE STUDY OF CRIME AND DEGENERATION FROM A MEDICAL STANDPOINT.*

By WILLIS S. ANDERSON, M.D., Detroit, Mich.

MY object in presenting this paper is not to offer anything distinctly new or to favor any preconceived theory; but rather to bring together certain facts from various sources and to draw such conclusions as the facts would seem to warrant.

We must assume for the purpose of our study that mental acts have a physical basis.

Since the days of Ferrier, whose experiments confirmed the works of Fritsch and Hitzig, of Berlin, the localization of brain function has been well established. It has come gradually to be acknowledged, with the accumulated evidence derived from the study of the lower animals and man, both in health and disease, that all our mental acts have a physical basis, in the sense that mentality is accompanied by a chemical change and a structural rearrangement of the molecules of the nerve cells. Hodges, in the study of fatigue, found an actual change in the brain cells following activity, that disappeared after a period of rest.

There are some who do not believe in this newer physiology; but the evidence derived from competent observers seems to warrant us in accepting this doctrine as the most rational explanation. It was formerly believed that our passions, such as hatred, love, fear, and the like, as well as reason, were confined to man; but the study of the works of Romanes, Lubbock, Darwin, and many others, convinces us that these qualities are common to the lower animals.

It is now generally accepted that the mental acts of animals, children and adults differ not in kind, but only in degree; that the same laws that govern our minds govern those of animals; and that similar chemical and molecular changes take place in the brains of both men and animals. If these facts are true, the study of crime and degeneration has a new interest, and much can be gleaned from the psychological study of animals and man.

The study of criminals and degenerates has been mainly along two lines: first the somatic or bodily anomalies; second, the psychological peculiarities. Lombroso was the first scientist systematically to study the physical peculiarities of degenerates, and his tabulations of the various measurements of criminals and the insane form an interesting study.

It would seem from the study of the writing of the Italian school that abnormalities in general, and those of the head in particular, were more common in criminals than in normal individuals. The cephalic indices are greater, the prognathous jaw and the atypical or projecting ears more common than in the normal.

The committee appointed by the British Medical Association to investigate the development and condition of the mind among school children found that ear defects were frequently associated with nerve defects and mental weakness. Dr. Langdon Down finds a resemblance between feeble minded children and the various ethnic types of the human family, especially the Mongolian and Negroid.

However attractive statistics and measurements may be, we must not forget the importance of racial characteristics, the effect of diseases, both prenatal and postnatal, on the physical development of the individual. It is also important to remember that apparently normal persons may frequently have one or more of these degenerative marks. It would seem that one is justified in concluding, after taking all facts into consideration, and from the study of a large number of cases, that the criminal, the insane, the idiot, and the feeble minded have physical anomalies oftener and more highly developed than normal individuals.

The more recent studies of criminology have been along a psychological line, rather than by the observation of the purely physical anomalies. It is as impossible to define sharply the limits between a normal and an insane or a criminal person as it is to understand accurately the difference between the diseased and the healthy action of cells.

As Max Nordau says: "The difference between disease and health is not one of kind, but of quality. There is only one kind of vital activity of the cells and of the cell systems or organs. It is the same in disease and in health. It is sometimes accelerated and sometimes retarded, and when this deviation from the rule is detrimental to the ends of the whole organism, we call it disease."

So it may be said with criminals. It is impossible to define the limits separating normal from degenerate persons. All mental processes are governed by the same laws, and all of us have at some time in our existence criminal tendencies; but it is only when our evil propensities become detrimental to the community in which we live that we are considered criminal.

Let us consider the evolution of crime, in order that we may rid ourselves of the idea that those acts which we are accustomed to call criminal are confined to the human species. Animals low in the scale of life are prone to commit such criminal acts as infanticide, murder and thieving. Snakes very often devour their young. Lubbock cites instances where bees and ants kill those of other species for the purpose of robbery. Romanes, in his "Animal Intelligence," gives any number of instances of crime committed by animals. Speaking of a certain species of ants, he says, judging from experiments, it would seem that hatred was a stronger passion than affection, while in other species sympathy and affection seem to be more highly developed. Audubon is reported as having observed the thieving propensities of birds. Many species are habitual thieves and often secrete articles apparently of no value to themselves. The tendency to steal and to hide things is one of the strongest traits of the wolverine. Rats, mice, wolves, rabbits and birds have been seen to kill those of their own species. Dogs have been known to slip their collars, and go miles to kill sheep, then wash the blood from their bodies in a stream, return before daylight and slip on their collars. Monkeys many times will kill their young, when tired of carrying them. They are also fond of deception and are great thieves. Many animals develop uncontrollable passions, and while infuriated often kill those of their own species or even family.

While these facts and many others have been observed, it is true that the maternal instinct is highly developed in animals, and that affection is so strong in some that they will die for or in defense of their own species, and in some instances those of other species. Though some of the acts mentioned may have been done in self-defense or self-preservation, there are many apparently purposeless acts against the natural instincts of animals that may surely be classed as morbid.

Turning our attention to the uncivilized races of men, we find crime especially frequent. The primitive tribes, as a rule, place but little value on human life, especially on those of women and children. Wood, in his "History of the Uncivilized Races of the World," cites any number of instances to show the criminal tendencies of the savage. Some of their crimes are associated with their religious or superstitious beliefs; but many seem to be the natural result of unrestrained animal passions. I have been told by one living among our American Indians in Idaho that infanticide is common.

The study of childhood offers much that is of practical as well as of scientific interest. The psychology of children occupies a middle ground between that of the lower animals and the adult man. It may not be pleasant to some to associate our babies with the lower animals; but it is, nevertheless, true that a close study of human embryology and the psychology of childhood teaches us that there are definite relations between the workings of the animal and infant mind. An infant at birth has its animal instincts highly developed, and in gesture, mimicry, and instinctive movements bears a close resemblance to the monkey. As the minds of children gradually develop, those qualities which are prominent in criminals and degenerates are the first to evolve. The idea of self enters more largely into all their acts than in normal adults. The emotions of the child are more easily aroused and less under the control of the will than in later life. Attempts to injure those around them are very common during fits of anger. Petty thieving of tempting morsels, of playthings and of similar articles and the practice of lying are common, even among carefully trained children. Capital crimes are not unknown among children. Murder and assaults have been reported many times. Children have a very imperfect idea of ownership and responsibility. Deceit, vanity, pride, superstition and cruelty are common traits in early life. These qualities, so undesirable in adults, are usual in children; and an exaggeration of these very traits in criminals marks them as vicious members of the community.

Idiocy, feeble-mindedness and epilepsy are accompanied by mental impairment, and often lead to crime and acts of violence. These affections may be due to congenital defect, to injuries, or to disease. Emotional instability is common among criminals, and often develops while they are secluded in prison. They frequently have periodic explosions that resemble epilepsy and which, like that disease, are more frequent in hot weather. One observer states that four per cent. of the criminals under his care were subject to violent fits of passion; among women these attacks are more common during the menstrual period.

Lombroso has pointed out that those regions in Italy that produce the most epileptics also produce the largest number of criminals. The relation between insanity and crime is an important one, although too large a subject to be considered in a paper of this kind. Those crimes that lead most often to insanity are potent agents in the production of crime. For instance, syphilis, alcoholism and sexual excesses are responsible for much of our insanity and our crime.

Jacobi says: "The constitutional criminal is a tainted individual and has the same relation as the epileptic to convulsions. The essential reason of abnormal brain action is abnormal brain structure." Later he says: "There is no especial type of insanity or of criminality. There is but one thing fixed, that is, the relation of cause and effect, the correlation of physical causes and mental and moral symptoms."

Lombroso, in his "Men of Genius," and Nordau, in his "Degeneration," give any number of examples of excessive nervous and mental action in men and women who have been prominent in their respective fields of activity. While it is true that Nordau has exaggerated the condition, it is, nevertheless, a fact that the history of poetry, art, music and literature is filled with examples of men and women who bore distinct marks of degeneration. Many inherited insane tendencies, some succumbed by reason of disease, overwork or dissipation. According to one authority, insanity is forty times more frequent among criminal than among average men and women.

We can trace in all individuals a process of evolution in the building up of their natures. Animal instincts are highly developed at birth, next intellectual power is added, and finally moral and ethical conceptions help to round out a man's character.

That it is possible to have arrest of development during any stage is apparent, just as there may be arrest of development during the embryonic stage, leading to congenital anomalies. If the process of evolution is checked in early childhood, only the animal instincts exist, and idiots and imbeciles are the result. If the arrest takes place later, we have impaired mental power or feeble-mindedness. If the arrest or atrophy is postponed until manhood is reached, we may have intelligence, but no moral sense. There are in society to-day many moral imbeciles, whose intelligence disguises them from the world until they commit some heinous crime that reveals their true character to society.

Heredity exerts a marked influence in the production of criminals. Just as physical and mental peculiarities are transmitted from parent to offspring, so moral and criminal tendencies are likewise inherited by children of degenerate parents. Some would explain these apparent transmissions of criminal tendencies by environment, but after considering all points there seems to be no doubt that criminal tendencies are actually transmitted. We do not mean by hereditary transmissions of criminal tendencies that parents must have been actual criminals in a legal sense, or that the children are; but that the inebriate, the epileptic, the insane, the morally depraved, beget children that are deficient morally and are prone to drift into criminal life, without regard to environment.

The Jukes family, as studied by Dugdale, is an excellent illustration of the influence of heredity. From the head of the family, Max Jukes, a great drunkard, descended, in seventy-five years, 200 thieves and murderers, 280 invalids attacked by blindness, idiocy or consumption, 90 prostitutes and 300 children who died prematurely. Out of 700 descendants carefully studied, but few were honest. Of the men, not more than 20 were skilled workmen, and 10 of these learned their trade in prison.

It has been observed that criminality, like idiocy, tends to run in the line of the eldest sons. Morris gives instances where, for four generations, marks of degeneracy were plainly evident, and with the fourth generation the race became extinct. He also points out the tendency to degeneracy in children of intemperate parents.

It would be interesting to study more in detail the influence of such diseases as syphilis, tuberculosis, alcoholism and meningitis in the production of abnormal conduct. That these and many other affections are important can hardly be doubted after studying carefully the histories of many criminals, who, either by inheritance or from acquired disease, have dyscrasiae, which enfeeble them physically and render unstable their nervous systems. We must not infer from this study that criminals and degenerates can be arranged like pathological specimens in a museum each labeled as a distinct morbid entity, with a proper diagnosis, and all dependent upon actual disease. We must remember that environment, education, association and climate bear an important relation to vicious conduct; and it is only by weighing these various factors in each individual case that a scientific diagnosis can be made.

The conception of crime on the part of many reminds one of those days of superstition and ignorance when those affected with insanity, epilepsy, chorea and similar diseases were considered to be bewitched by the devil, and therefore were cast into prison, hanged and even burned at the stake. The history of witchcraft in our country is a blot upon old New England. To-day all is changed. We have asylums for the insane, colonies for the epileptics and homes for the feeble-minded, while the aim is to reclaim these unfortunates and to return them as useful members of society.

From our experience in the past in dealing with those mentally impaired, and from our present knowledge of the normal and diseased workings of the brain, can we not apply similar methods to the study and care of criminals and degenerates?

This problem is of vast importance to society and the state; and it behooves the medical profession to give the same study and thought to it as they would give to mental diseases in general. It is necessary that we keep in touch with this problem in order that we may give an intelligent opinion and wisely direct legislation along lines that are practical, scientific and just.—The Physician and Surgeon, August, 1896.

* Read by title before the Michigan State Medical Society, at Mount Clemens.

The sufficiency of the British government tests on the safety of petroleum as supplied to the public for burning in lamps has long been contested by experts and suspected by users. Mr. J. A. Wanklyn writes: "Petroleum is dangerous when it contains more than the minutest traces of the very volatile hydrocarbons, and it is safe when such hydrocarbons are absent or inappreciable. If our government does its duty, it will insist upon a flashing point of 105° at the very lowest; and, indeed, even a higher figure than 105° would be desirable. And certain other guarantees might also be enforced. With reference to the statements that serious practical difficulties stand in the way of forbidding petroleum of low flashing point, I am able to assure you that there are no difficulties which cannot be easily surmounted." A great deal of light oil is now being used for engines, for blowpipes, and for other purposes in the workshop, and there is liability that some of these light hydrocarbons may get mixed with the presumably safe burning oil.

RECEPTION OF THE EMPEROR AND EMPRESS OF RUSSIA BY THE FRENCH ACADEMY, OCTOBER 7, 1896.

THE salons now open contain few pictures that reproduce episodes of the Franco-Russian fetes of last October, and, further, the compositions in which we do find reminders of the visit of the young imperial couple have neglected the magnificent and stirring spectacles for scenes of quietness and simplicity. Among such pictures, the most tranquil is undoubtedly that representing the reception of their royal highnesses Nicholas II and Alexandra Feodorowna by the French Academy.

Its setting, the small Salle des Quarante, with its dark green paper dating from 1840, and its sober and severe ornamentation, gives it an air of gravity and contemplativeness. The portrait of Richelieu and the marble busts attentive upon their brackets to the academic discussions give it solemnity without any detriment whatever to the serenity of the place.

There is no parade in this picture, any more than there was in the real scene. At the desire expressed by the Emperor, the coats with green palms, the swords with mother-of-pearl hilt, and the feathered bicorn remained in the wardrobe of the Immortals. The academicians have their habitual attitude in the frock coat of the working sessions, and the word "Aulner" that the perpetual secretary is about to submit for discussion, in order that this day too may furnish its contribution to the advancement of the dictionary, is no great thing to symbolize here.

THE EMPEROR AND EMPRESS OF RUSSIA AT THE FRENCH ACADEMY.
PAINTING BY M. BROUILLET.

It was thus that Nicholas II desired it, and the Academy carried out his wish with scrupulous care.

The entire palace offered an oasis of absolute calm, an invitation having been addressed to its ordinary inhabitants to stay at home from the arrival until the departure of the august visitors, that is to say, from half past four until half past five.

One lived here for an hour isolated from the flourishes of trumpets, the cheers, the cavalcades and the clamor of the exterior. The only sign of gala that appeared at the Mazarin Palace was a marchioness standing at the door of the secretary's office.

Peter the Great, at the time of his unexpected visit in 1717, was received still more simply. In the hall of sessions he found but two academicians. On October 7 last his successor met with twenty-nine Immortals, and this was not the full Academy. Cardinal Perraud and MM. Emile Ollivier, Challemel Lacour and Paul Bourget, absent or sick; and Anatole France, Gaston Paris and Costa de Beauregard, not yet officially received, did not figure in the company.

The session had none the less an air of solemnity that was amiable and imposing in its simplicity. MM. Rambaud and Hanotaux received the President of the republic and our august guests at the door of the secretary's office, at the angle of the second court of the Palace of the Institute. The Empress ascended the stairs on the arm of M. Felix Faure, and it was at the entrance of the first Salle des Pas-Perdus that the President of the republic presented M. Legouvé, president of the office, M. de Vogüé, chancellor, and M. G. Boissier, perpetual secretary, to the sovereigns. In the Salle des Quarante, toward which M. Legouvé led the illustrious visitors, stood MM. Bertrand, De Bornier, Meilhac, Sorel, Lavisse, Halévy, Coppée, Sardou, Houssaye, D'Audiffret-Pasquier, Loti, Mézières, Cherbuliez, De Freycinet, D'Haussonville, Hervé, Thureau-Dangin, Pailleron, Sully-Prudhomme, Claretie, De Broglie, Brunetière, De Hérédia, Duc d'Aumale, Gréard and Lemaitre. While the Emperor and Empress and President Faure were seating themselves in the three arm chairs placed opposite the desk, the members of their suite occupied the circumference and the entrance of the hall of sessions of the Academy. This hall was invaded by a staff that would have been unable to find space in the first. M. Legouvé then opened the meeting and saluted the Russian sovereigns in these words:

"Sire, Madam:

"It is nearly two hundred years ago that Peter the Great, in the course of his voyage to Paris, arrived unexpectedly one day at the place where the members of the Academy were assembled, seated himself familiarly among them and mingled in their work.

"This visit, so full of cordiality, has remained in our archives as one of our most pleasant remembrances.

"Your Majesty is doing still more to-day; it is adding an honor to an honor in not coming alone. (Turning toward the Empress): Your presence, madam, is to introduce into our grave session something unaccustomed—a charm.

"How can we thank your majesties for deigning to take a seat in this little hall? The best way, it seems to me, is to give you an idea of what takes place herein, to allow you to witness one of our ordinary sessions, and to show you the academicians at work. The Emperor of Brazil once took part in our philological discussions; Grand Duke Constantine seemed to take pleasure in them; and this permits us to hope that your majesties will not greatly regret the few moments that they will have been kind enough to devote to us, and of which we feel the full value.

"Will it be permitted me to say so? This expression of sympathy is addressed not only to the Academy, but to our national language itself, which for you is not a foreign tongue. Such kindness well emboldens us. It carries us back to your immortal ancestor. To us, his visit is connected with yours, and in our gratitude we dare to address a prayer to your majesties: On this day, let us celebrate in advance the bicentennial of the cordial friendship of Russia and France."

After this address, M. François Coppée read a poem written for the occasion.

During the reading of this the sovereigns did not take their eyes off the poet.

The perpetual secretary afterward called his colleagues to work. In a short and clear address, he presented a few general considerations upon the dictionary of the Academy, recalling its seven successive editions, with their raisons d'etre, and, after this elucidation, brought the word "Aulner" into discussion. A rapid exchange of views was all the work accomplished.

At a quarter past five, M. Legouvé closed the session. The roll of those present was carried to the sovereigns with the request that they should affix their signatures, according to custom. Then the president proceeded to present his colleagues, the majority of whom respectfully kissed the Empress' hand. The imperial couple accepted a volume containing M. Legouvé's address, M. Coppée's poem and a paper entitled Peter the Great at Paris in 1717, the author of which, M. d'Haussonville, was not able, for want of time, to read it during the session.

The august visitors left the Academy with the same ceremonial as at their arrival, leaving behind them a kindly remembrance. That which they carried away with them, we dare say, was not one of the least agreeable of their stay in Paris; and the picture in which M. Brouillet has so exactly portrayed this session will doubtless cause as much pleasure at St. Petersburg as it has with us.

M. Brouillet has selected the moment at which M. Legouvé is delivering his address to their majesties. The figures of the painting and their scrupulously observed attitudes make a series of perfect portraits of this work. All the details are of irreproachable accuracy, and the whole gives an idea of calmness and repose.—Le Magasin Pittoresque.

STOCKHOLM.

CUT in on all sides by the sea, Stockholm is built on numberless islands, like Venice, but, unlike that ancient city, it is closed in by rocky heights in the immediate neighborhood. At the same time it is one of the most beautifully situated, most artistically built and historically most interesting towns of the earth.

On one side of the Ritterholms church is the bronze statue of the founder of the city, Birger Jarl, not a king, but a king's sire. This part of the town is the most ancient. Its site was particularly suitable, as an enemy approaching by sea from the Baltic could easily be stopped by putting a chain across the harbor. The town was often taken in the middle ages, and was won back again. A cloister which once stood on the site of the Ritterholms church was then the place of refuge for the beleaguered queen and her suite. On the other side of the Ritterholms church, in front of the former House of Lords, is a bronze statue of King Gustavus the First, holding the scepter in his right hand. The church itself, with its mausoleums, holds the royal burying vaults. There sleep Marshal Bernadotte, Charles the Fourteenth, with his descendants, the kings of the house of Holstein-Gottorff, the Carlovingians, and those of the house of Pfalz-Zweibrücken, Charles the Tenth, Eleventh and Twelfth, and finally their greatest king, Gustavus Adolphus, in the midst of his soldiers; the numerous flags on the tombs of the Baner and Torstenson are proofs of former renown in war. The dainty Gothic church is at the same time the Westminster Abbey of the Swedes. The names and coats of arms of the Knights of the Seraphine order are painted on the walls. Among these knights there is also a woman, the Czarina Catherine the Second. A quaint sight, especially if we remember what were her thoughts concerning the Swedes of her time and concerning their king, Gustavus the Third.

The statue of this monarch, who had such a tragic death, is on the east side of the royal palace, where you emerge in front of it, ascending from the sea.

In the night of the 16th of March, 1792, the fatal shot fell from Anckarström's weapon in the royal opera house. This gigantic building stands on the Gustavus Adolphus Square, facing the North Bridge, the Holy Ghost Island, and the northwest front of the royal palace. The latter is one of the finest buildings of the world and one of the largest castle residences. It is built nearly square, and on the slightly longer side it measures 120 meters. The style is Italian Renaissance. The builder was Nicodemus Tessin, a Frenchman of a family that gave to Sweden both artists and statesmen. The northeast front holds between two projecting wings a beautiful garden terrace. In the south the steeple of St. Nicholas church stands aloft. This church had formerly the highest steeple of all Scandinavian churches. But after crumbling down several times, and being built up again, it was finally reduced to more modest dimensions. The government buildings of Stockholm, too, as particularly the museums dedicated to the Princess Sophia, are wonderfully built. Behind the palace is the fine German church, and by it the market place which saw the fight of the Swedish citizens against their nobles.

Of surpassing beauty are the surroundings of the city, particularly the zoological garden, with the careless, gay life of its summer nights. Here stands the bust of the Scandinavian poet, Charles Michael Bellmann, who celebrated these unrestrained frolics. He was the descendant of a German immigrant. In the south there is the Mosebakken Park. To the densely populated workingmen's suburb, Sodermalm, you are raised by the great Catherine elevator. By the bridge in front of this is an equestrian statue of the first king of the Bernadotte family.

Picturesque popular dress gives life to the streets of the capital, and if the snowshoed Laplander

VIEWS OF STOCKHOLM AND SURROUNDINGS.

must be sought further north, the peasant girl with the high white headgear, and the many colored apron over a red skirt, is much more frequently met. Specially fine is the dress of the valley girls, with their dark brown conical cap and the apron of ten colored stripes; they are the daughters of those valley men with which Gustavus Vasa drove the armored knights and archers of Christian the Second from the land.

The first royal Vasa rests in Upsala. The superb cathedral is the finest ecclesiastical building of the North, and at the same time one of the oldest. A shepherd's staff which is kept there behind the altar was given to the local archbishop by Pope Alexander the Third, before whom Barbarossa kneeled in 1177. There also sleeps the third royal Vasa, John the Third, with his Polish wife, the beautiful Catherine Jagellonica, and the founder of the race, Gustavus the First, with his three spouses, Catherine of Saxe-Lauenburg, Margerita Seijonhufond, and Catherine Stenbock. The second of these is the ancestress of Gustavus Adolphus.

Close by the cathedral is the university building. Before it stands the statue of the poet and historian, Eric Geijer. The studies at Upsala are rather prolonged. The university is very rich, and owns, among other possessions, the whole of Gustavus Adolphus' family estates. The students are divided according to nations, each nation having a splendid club building. The choirs of these nations give excellent recitals, and Terpsichore, too, is greatly honored. High above the town rises the remaining wing of the old castle, where Gustavus Vasa held his parliament, and where his insane eldest son, the peasant King Eric the Fourteenth, had the last Stures murdered. Some considerable distance further north lies the ancient village of Upsala, with its royal tombs in mounds, the only monument in remembrance of the vanished temples of the Norse Odin worship.

These are some of the historical shadows that flit over this ancient city. He who visits the Swedish capital, with its Scandinavian exhibition in summer, will enjoy beautiful days under the cool summer sky of this most interesting town. Beauty of nature, historical memories, and the amiability of the people together effect an ensemble unequaled in its kind.

Our illustrations are taken from the German periodical Ueber Land und Meer.

ALASKA DEVELOPMENTS.

The year 1896, however depressing elsewhere, was pregnant with richness for Alaska, says the Iron Age. The output of gold ran up to $5,000,000, or double that of the previous year, and the promise for 1897 is $12,000,000. Last year 11,000 persons, of whom 90 per cent. were miners, moved into the province, 8,000 going to the upper Yukon and 1,000 to Cook's Inlet. Fifteen thousand are expected this season on the Yukon alone, and all the agents, shippers and consignees are preparing for the rush. Bureaus of information are already open at Seattle, Juneau and other Pacific coast stations. New steamers are being fitted up for the trade and liberal schedules prepared. A large smelter is to be built at once at Seattle to treat sulphurets and refractory ores. Many miners, who have been wintering at Juneau, Sitka and Wrangell, are preparing for departure to the mines, and the advance on the Yukon has already begun.

The journey over the divide and down to the chain of lakes is not the hardship now that it was once. Late last fall the last men out discovered a short and easy route across the interior plains which can be traversed with pack mules in 30 days or less, and next spring, as soon as the rush begins, goods will be hoisted over the summit of Dyea Pass by block and tackle, and the cost of transportation from the steamer landing at Chilcoot to the head of barge navigation will be only 5 cents a pound, instead of $4, as two years ago. Later on a cog railway, like those which surmount Pike's Peak and Lookout Mountain, will be constructed, and then the difficulties of the 1000 mile journey from the coast to the diggings will be minimized.

Ten thousand prospectors in a given area, however extended, can accomplish much. Consequently, remarkable development resulted last year, not only on the upper Yukon placers and old quartz ledges along shore, but all over the golden provinces at points widely scattered and many hundred miles apart; at Norton Sound, at Unga, in the Aleutian peninsula, up on the British boundary at the headwaters of streams, and all along the Yukon River down to its very mouth.

Most of the propositions were low grade, but in not a few richness was found in nuggets whose maximum weight was 5 ounces.

Practically all of the gold produced last season in the Yukon region came from half a dozen little creeks and gulches tributary to Birch Creek and to Forty Mile and Sixty Mile Creeks. Between the last two points a winter camp of 800 souls called Klondyke has sprung up, so that the three populations of Circle City and the other two aggregate about 3,000 souls. At Circle City all the trades and professions are represented, while comfortable two-story frame buildings are rapidly supplanting the original log cabins. Among the most noted of these creeks are Mastodon, Deadwood, Bushnell, Discovery, Mammoth, Greenhorn, Mission, Goldbottom, Eagle, Bonanza, Preacher, Minuke and Independence. Minuke Creek is a new location of rare promise some 300 miles below Circle City on the Yukon. The Birch Creek district is 100 miles up stream above Circle City, which is the principal winter headquarters for miners. There is a portage of 12 miles first, and then a push up creek with bateau. This district is in disputed territory, and some 200 or more valuable claims are involved. Hence it would seem to be imperative that the boundary line between Alaska and British Columbia be confirmed without delay according to the joint survey of the two countries, as urged by Special Commissioner Hamilton, secretary of the North American Trading and Transportation Company, who is now in Washington for the purpose of persuading Congress to act. The Birch Creek discoveries were phenomenal, yielding in some cases $20 to $30 the pan, and $50 to $100 a day per man. With such lavish returns, miners could afford $10 per day for expenses, board and washing included. The total output for the season credited to this district was $2,500,000. Miners would not look at anything which offered less than an ounce a day. In this stretch of country there are a dozen rivers, each of which is as large as the Ohio, with tributaries innumerable called creeks. Preacher Creek itself is 700 miles long. No wonder prospecting was hard in the beginning and the outlook discouraging, with such magnificent cross country distances ahead before getting down to the task of removing the superincumbent detritus and débris from the gravel beds of the streams. But there is not a foot of their banks now found which does not contain auriferous soil; not the creek bed and adjacent bars alone, but ground 75 yards off from the water-courses is found to be rich in gold. Under the glacial drift old channels are often found which were never suspected from the surface indications. Of course massive quartz ledges must exist from which all this float gold emanates, and when these are finally located, as they soon must be, with the 15,000 miners who are expected on the ground the coming summer, the pounding of hundreds of stamps will disturb the quiet of the ancient Mastodon range. One such ledge, known as Quartz Mountain, three miles above 40 mile post, yields $11 per ton. There are several large trading posts besides business houses in this vicinity, each of which is the outfitting and distributing point for a mining district of its own, and they all have supply steamers running regularly down the Yukon. There are more steamers on the upper Yukon to-day than there are on the upper Mississippi.

Gold was first discovered in this region in 1880, but it is only for the past three years that the mines have been operated in force. The short working season and the terribly hard winters have alone kept off a rush to which that of California in 1849 would hardly be a circumstance. Henceforth, mining in Alaska is to be made comparatively easy.

Of the older quartz mines along the southeastern coast from Sitka to Juneau, and to nethermost parts, several of which, like the Treadwell, Mexican, Silver Bow, and Bald Eagle, are celebrated, they simply increase in richness as they develop. Six hundred stamps or more keep busy crushing out ore, which last year yielded $2,500,000 of gold bullion. Included are those operated by the Boston & Alaska, Nowell, Berner's Bay, Alaskan, Alaska-Commercial, Funter Bay, Juneau, Junlin, Apollo and Ebner companies, comprising in some instances a host of claims. Then there are the Unga, Admiralty and Green Island plants, and the large group of mines in the vicinity of Sitka, many of them of ancient date. With improved appliances for working, few fail to give satisfactory returns, and nowhere on the earth can better machinery and apparatus be found, such as gravity railroads, steam and electric tramways, several miles long, compressed air drills, snow sheds, hydraulic engines, etc. By the chlorination process the cost of mining and milling ore has been reduced as low as $1.08 per ton, with coal at $8. This is at Douglas Island. The coal bins of this concern hold 3,000 tons. In these days, mining operations can be continued all winter, since shafts have been sunk to depths where cold does not interfere with work. Some shafts are now down 1,000 feet. On the strength of present showing many important transfers of properties have been effected since fall. Four claims in the Sum Dum district, directly opposite the Bald Eagle, on Holkham Bay, have been sold to a French syndicate for $150,000. The Horrike and Mexican mines on Berner's Bay were sold to Portland, Ore., capitalists for $60,000. A Chicago syndicate paid $200,000 for the Funter Bay and Mountain King group of 11 claims, which are connected with the beach by a narrow gage railroad 2 miles long. The noted Willoughby mines went for $175,000, it is said. The Bonnie Brian went to St. Louis parties for $75,000. All the ledges in the vicinity of Douglas Island carry a good deal of free gold, and new discoveries and new claims are being located all the time. At Unga, in the Aleutian archipelago, some rich leads have been struck, and 20 new buildings have gone up. Considerable prospecting has been done with excellent promise on Kadiak, Afognak, and Whalcom Islands. On the latter, a free milling quartz ledge has been struck, which assays from $20 to $295 per ton. Ketchikan, between Nowell and Berner's Bay, is a new discovery which has been purchased by San Francisco parties, who will put up a stamp mill in the spring. The Apollo Company's output is said to average $40,000 per month.

Next in importance to the Yukon diggings are the Cook's Inlet placers, from which $175,000 was taken out last summer, chiefly from Turnagain Arm at the head of the bay, where the mining towns of Hope City and Sunrise are located. Other locations are at Chintna and Tyonic, further down, and at Anchor Point, near the mouth of the inlet. All the diggings are easily accessible by ocean steamers or vessels; the climate is mild; the vegetation luxuriant; fish, clams, and wild game abundant; and all the hydrographic conditions most favorable. The consequence was that the diggings became overcrowded last year with inexperienced persons indifferently equipped; and as it cost more to wash out the gold by hand than the gravel panned out, most all of the adventurers came home destitute or empty handed. But the gold is there, sifted all over the country in minute particles, 3 feet beneath the surface and averaging 50 cents to the square yard. Persistent prospecting has discovered this fact, and a big syndicate has been formed to get it out, called the Alaska Gold Syndicate Company, and their headquarters are in New York. The early spring proximate will be signalized by the employment of new mechanical processes which will render available and profitable large areas of goldbearing sand and gravel beds which heretofore it has not paid to work. Hydraulic machines, each capable of doing the work of 250 men, will wash out gravel at a minimum cost of 3 cents per cubic yard only; and as the placers yield from 50 cents to $3.50 per yard, the profits anticipated are large.

Manifestly, Alaska is looking up. Of all places in our land it feels the financial pinch the least. The town of Juneau has grown to large proportions on the strength of the boom. Seattle feels the electric energy in every part. Several lines of coastwise steamers connect Seattle and intermediate ports with Unalaska. Three lines of well appointed freight and passenger steamers ply regularly to trading posts, mission stations and populous towns on the upper Yukon. Regular communication is kept up between St. Michaels in Bering Sea and San Francisco, and there is regular monthly mail service overland to Circle City and the gold diggings. It was not so ten years ago.

SOLANDRA GRANDIFLORA—FLOWERS CREAMY WHITE.

SOLANDRA GRANDIFLORA.

This fine climbing plant, now rarely seen in gardens, is indigenous to Jamaica, where it goes under the name of the peach blossomed trumpet flower. Under cultivation the flower is white, with a purple tinge on the interior of the tube, but under the intense light of the tropics it is of a pale flesh color. It first flowered in this country at the Royal Gardens, Kew, in 1818, the figure given in the Botanical Magazine of that year having been taken from a flower furnished by Mr. Aiton. It also flowered in Mr. Salisbury's garden at Mill Hill, at about that time, and produced fruits there. The genus was named in honor of Dr. Solander, a pupil of

Linnæus', and fellow traveler of Sir Joseph Banks in his voyage to the South Seas. Cuttings of ripe wood strike readily in heat; and the cultivation of the plant is not difficult, provided a well drained fairly roomy border and plenty of head room are given it in the stove. We are indebted to Mr. G. Bolas, gardener at Hopton Hall, Derbyshire, for the flower from which our engraving is taken, and the following particulars: "The plant is of interest from the time the buds begin to expand. The change in the color of the flower is very remarkable, these turning from a pale olive green tinted with yellow to a creamy white on the fourth day. I received the plant in the summer of 1896, looking like a dried stick, with no signs of life in it, it having traveled, wrapped in a newspaper, from the island of Madeira. The plant had been stuck into the ground some days in a garden near Shrewsbury before I got it, and this gave me a hint as to the kind of treatment necessary to flower it."—Gardeners' Chronicle.

LATHYRUS SPLENDENS.

THIS handsome creeper has been in flower for some time past in the Cape House at Kew, England, where its brilliant scarlet flowers attract much attention. It has been likened to a sweet pea, but to our thinking is more like the perennial pea. It is a native of California, and is known as the "Pride of California." For the specimen whence our illustration was taken, we are indebted to the authorities at Kew.—The Gardeners' Chronicle.

LATHYRUS SPLENDENS—FLOWERS SCARLET (KEW).

THE ARCTIC SEA ICE AS A GEOLOGICAL AGENT.*

By RALPH S. TARR.

NATURE of Sea Ice.—Floating in the Arctic waters there are two kinds of ice—the sea-made and the glacier ice. The former develops in the autumn, first freezing over the protected fjords and bays and later covering the greater part of the Arctic Sea. As it freezes it incloses the glacier ice and consolidates the entire water surface into one mass of ice, which remains in this state until spring. The sea-made ice attains a depth of only a few feet, averaging perhaps fifteen or twenty feet. The wind, waves and currents move it about somewhat even in the winter, and by breaking it and piling the fragments on one another make the surface very irregular, greatly increasing the depth of some of the cakes. Moved by the tides and winds, it grinds against the shore and the shallow bottom, thus doing much work of erosion. In the spring, under the warmth of the rising sun, it commences to melt and goes floating away to the southward, where it finally returns to the liquid condition. Then, hundreds of miles to the southward, the individual cakes and scattered floes may introduce the conditions of the ice-bound sea of the North into the southern latitudes even late in the summer.

Nature of Glacier Ice.—Near the glaciers which end in the sea the surface of the fjords is littered with ice that has been derived from the glacier front. The melting in the warmth of the sun, the movement over an irregular bottom or the buoyancy of the water, make cracks in the glacier; and the action of the waves and sea water at its base undermines the ice cliff, so that there is a constant cracking and falling of bits and blocks of glacier ice. The air is constantly filled with the reports of varying intensity which accompany the breaking off of ice. Now and then a large piece, perhaps a great section of the glacier front, falls away and enters the sea as an iceberg.

This glacial ice, of whatever origin, incumbers the water of the fjords so that navigation even in a small boat is usually difficult. Slowly the ice drifts out to sea, for the summer winds prevail from the glacier-covered land, and hence there is a balance maintained. Were it not for these offshore winds, the glacier would soon fill the fjord with ice, and not being able to discharge its cargo, would be obliged to push farther out to sea. The sea ice is made in winter; the glacier ice is mainly supplied in summer. During the spring and early summer the movement of the sea-made ice is active, and then, when it has disappeared, its place is taken by the supply from the glacier.

Influence of Sea-made Ice on Erosion.—The sea-made ice of winter, covering the bays from shore to shore, protects the coast from the action of waves, and hence for the greater part of the year prohibits this form of erosion. Even when the ice is broken up and floating away, it protects in nearly the same manner; for the ice cakes and floes prevent waves from forming, and destroy those that have already been formed elsewhere. Even when the wind was blowing, while our ship was in the open sea off the Labrador coast, there was only an almost imperceptible swell, the remnants of the nearly destroyed waves of the ice-free, open water. However, when the ice cakes are more scattered, the waves use them as effective tools, hurling them against the coast and grinding them up and down upon it. Moreover, in the last stages a rim of ice clings firmly to the rock at high-tide mark, and no doubt the waves use this in places as a means of prying off fragments of rock.

It would be difficult to balance the protective and destructive action of this sea ice, but I believe, on the whole, that the average is in favor of protection. Nevertheless, the ice is used as a very effective tool, not merely by the action of the waves, which hurl the individual blocks against the shore, but chiefly by the grinding action of the tide. As the water rises and falls the ice is constantly ground against the shore, and that, as a result of this, it is doing much work is oftentimes clearly illustrated. Nowhere was this better seen during my visit to the Arctic than on the southern side of Baffin Land in White Strait. There the tide rises about thirty feet, and the mud flats, when exposed to view at low tide, were seen to be pitted and gouged in a manner quite closely resembling the surface of the mud flats on the Massachusetts coast after the clam diggers have left them. Carried in by the tide, the ice cakes strike against the muddy bottom and dig a hole, thus stirring up considerable mud, which is driven about by the tidal currents. Stranded cakes were everywhere present, and that they were engaged in the transportation of rock material was often shown by the presence of good sized bowlders, deeply embedded in the mud, where they had been dropped by the melting of the ice.

In this same region the grinding and transporting action of the ice was shown by the bowlder beaches. At the head of narrow and perfectly protected bays, there were beaches of bowlders, averaging a foot or two in diameter, and beneath these, forming the bottom of the bay, was mud. No other agent than ice could possibly have placed these bowlders in this position, and upon the stranded blocks of ice there were some bowlders journeying toward the beach. Similar bowlder beaches were found in the valleys of the land, showing that when the land was formerly lower this same ice action was in progress.

There is another way also in which the sea ice aids in the work of erosion on the shores. The rocks of the New England coast are covered with a protective mat of seaweed, barnacles and other forms of life, while the Arctic shores are entirely free from this covering, except in the minute and most protected crevices. Because of the ice grinding on the shore, life is impossible in the intertidal zone, although at a short distance below this both animal and plant life are extraordinarily abundant. Lacking the protection of this organic mat, the rocks are open to the direct attack of the water, and its agents must, therefore, work with greater rapidity, in a given period of time, than they do upon a similar coast that is protected by organisms.

Erosion by Glacier Ice.—In a less noticeable way the action of the glacial ice is the same. It is used in the same manner as the sea-made ice, and adds to its efficiency both in protecting and destroying; but there are two additional ways in which the glacier ice does work of erosion after it leaves the glacier. In order to understand the first of these it is necessary to know how the icebergs are put forth into the sea. So far as I could observe, there are several ways in which the ice comes from the glacier front. As has been said, some pieces, usually of small size, drop because of surface melting and others fall because the sea undermines the ice cliffs. Besides these sources of glacier ice there is the effect of the water, which buoys up the front of the glacier until a breaking results, when bergs, usually of large size, proceed from the front of the glacier.

In some cases this process of iceberg formation happens very quietly, and the front merely cracks off and floats away; but much more commonly the breaking is accompanied by a very decided disturbance. The end of the glacier has attained an unstable position; melting or undercutting cracks off a fragment, and the accompanying jar causes others to follow. The air is filled with sounds, as if of musketry, and from the glacier front there is a constant shower of small pieces and large blocks. Whenever a great mass falls away, numbers of others equally large or larger follow very closely. These do not break and float quietly away, but actually fall forward into the water. Even though the crack started from the bottom, there is no other way for the bergs to fall than to go forward. They must then attain a stable position in accordance with their form, and this often causes them to roll over completely, and float away bottom side upward. So a newly born iceberg may move off from the ice front either upon its side, bottom or top.

Not only are icebergs of massive form sent off from the glacier front, but if they come from a place that has been sufficiently crevassed and melted into irregular outline, the jarring caused by the falling and overturning may in the end completely destroy the berg and leave in its place only a multitude of fragments. One may often see an immense mass fall off from the ice front, and as it turns and rocks, may observe it break, until finally the original berg is entirely destroyed. When the iceberg is more solid, although numerous fragments continue to drop from its surface as long as it moves, it rocks and rolls backward and forward, perhaps for a half hour, before finally becoming quiet, and every piece that breaks off from this mass adds to the cause of rocking.

From the mass of ice thus cast off from the glacier there is sent outward a water wave, high near the ice front, but reduced to a low, almost imperceptible swell at a distance of a few hundred yards. Following this are other ring waves caused by the rocking and continued breaking. Though low, these are very powerful, for, like the earthquake wave, they are deep seated disturbances, not superficial like the wind wave. When they reach the shore it is whitened by surf as long as the waves continue to arrive. Then, although the surface of the fjord rises and falls only very gently, the shore line resembles the storm-bound coast of the open ocean; and during a stay of several weeks in the fjord near the Cornell glacier, at the base of the Upper Nugsuak peninsula (lat. 72° 15'), these were the only good sized waves that we saw, near the head of the bay. The waves caused by the production of bergs furnishes an additional instance of erosional work which Arctic ice does. Similar though smaller waves are formed when an iceberg runs aground and begins to break because of the jar.

When a berg comes off from the glacier it falls into the sea and rises and falls as it rocks backward and forward. Possibly as it moves it strikes the bottom; and certainly, as a result of the disturbance which it produces in the water, it stirs up the materials forming the bottom. After leaving the glacier front, in the course of its life history, the berg, in all probability, becomes stranded once or perhaps several times. Each time it touches the bottom it strikes a direct and heavy blow, and then, breaking slightly as the jar passes through it, and perhaps even falling into fragments, it rocks backward and forward in its effort to regain a stable position, thus striking the bottom again and again, and undoubtedly stirring up much mud by means of the disturbance of the water. Even when not striking the bottom, a strong wave is sent down to the bottom, and by this also there must be a disturbance. That these movements of the iceberg are performing work of distinct importance is proved by the muddiness of the water near the stranded bergs. Also in the berg fjords there is always the evidence of floating seaweed which has been detached from the bottom by this means.

In the fjord which I studied in most detail an interesting adaptation of animal life to this phenomenon was observed. On the face of the nunatak between the two lobes of the Cornell glacier a colony of gulls had their breeding place. The moment the report of a falling berg of large size passed through the air these birds left the cliff, and the air was white with these graceful creatures, flying directly, and with much eager chattering, to the front of the glacier, where they settled on the surface of the water and obtained a feast of shrimps and mollusks which had been stirred up and raised to the surface on the detached seaweed. This grinding against the bottom, and the disturbance caused by the wave produced by the falling ice, not only does considerable work of erosion, but also destroys much life. Notwithstanding this constant destruction, and it is certainly very great, the fauna at the bottom of the fjord was found to be abundant and varied.

Transportation by Sea Ice.—The sea ice of all kinds is also doing a great work of transportation. During our

* From the American Journal of Science.

voyage along the Labrador coast we passed through an unusual amount of floe ice. Shortly after leaving the straits of Belle Isle we encountered it, and were then in the ice almost continuously until we left the American coast a little north of Cumberland Sound. For nearly one thousand miles we were in sight of floe ice, and we therefore had unusually favorable opportunities for observing the conditions of this agent. As would be expected, the great number of floes were pure and white; but there were many that were transporting sediment. Even when the ice was freest from foreign materials it was estimated that about one per cent. of the cakes carried debris of some kind. In some cases the ice was perfectly dirty and black with mud, so that at times we mistook cakes for seals and walruses. In other places, in smaller areas, fully fifty per cent. of the floe ice in sight was discolored by a greater or less amount of detritus. These dirtier areas were undoubtedly derived from near the coast.

Some of the material that was being transported by the floe ice was very fine in texture, and apparently had been drifted upon the ice by the action of wind; but much of it was too coarse for this origin, and pebbles were frequently seen upon the surface of the cakes. No doubt these coarser materials were this part raised from the shore by the ice as it came in contact with the coast or passed near it; but probably the material was more commonly furnished by rills and streams from the land. I am certain that in the distance of one thousand miles of ice-covered sea our ship was within sight of thousands of tons of sediment, which was of course being slowly distributed over the bottom of the sea as the ice drifted southward.

Transportation by Glacier Ice.—Not merely is the floe ice carrying much sediment, but notwithstanding the statements of others to the contrary, the glacier ice is also a very potent agent in this respect. Among the bergs seen in the south it was rare to find one that had sediment in sight; but no doubt these, which had been floating for months, or possibly years, had long since given up their rock burden to the sea. Along the Greenland coast, however, sediment-laden bergs were abundant, and this was particularly true in the fjords near the glaciers.

The sea face of the Cornell glacier, like that of most others on the Greenland coast, is made of clear ice, almost absolutely free from even the finest sediment, excepting near the land margin, and below the nunatak which furnishes a medial moraine. The same is true of the ice face wherever the glacier ends on the land; but near the glacier bottom, both on the land and in the fjord, the ice bears considerable debris. That this was true of the ice bottom in the fjord was proved by the evidence of dirt and bowlder covered fragments that were floating in the water of the fjord. Some of these were entirely black, and we mistook some low ice masses for islands because of their discoloration. Moreover, in one of the bergs which was actually seen to come from the ice front this fact was definitely proved; for when it came off it turned with its bottom side uppermost, and floated away as a dark, discolored fragment, derived from a glacier whose exposed front was remarkably white.

There are thousands of tons of bowlders, gravel and clay sent into the sea from the front of the Cornell glacier every year, and much of this passes beyond the fjord out into Baffin's Bay. The sediment supplied to Baffin's Bay is in no small part derived from the bergs that are discharged into it. Some of this may go for long distances, provided the berg is turned bottom side up, although even in this case the water furnished by the melting of the surface of the ice will after a while wash the sediment away. When the berg keeps right side up, as is commonly the case, the debris rapidly escapes into the sea; and before the iceberg has moved far on its journey only clear ice, which of course forms the greater part of the mass, remains to float away. This is no doubt the reason why the southern bergs, even when these have recently turned upside down, as is frequently the case, are found to be free of sediment. They may have started on their journey with tons of debris.

Effect on Climate.—This brief statement of the geological effects of the Arctic ice would not be nearly complete if its effect upon the temperature of air and water were not mentioned. It chills the ocean on the American side, where the movement of the currents is toward the south, and by this means lowers the mean annual temperature of Baffin Land, Labrador and even New England, as everyone knows. In 1896 this effect was very clearly shown. An unusual amount of floe ice in the month of July so chilled the water on the Labrador coast that the cod fisheries were nearly a failure, because the cod fish would not come into the cold water near the coast. It was also most strikingly shown in early September, when we left the Greenland coast in summer weather, proceeded toward the southwest, and as our first view of the Baffin Land coast saw a snow-covered land. An ice-covered country was warmer than a nearly ice-free land, which, however, was bathed in water that had been chilled by the ice of the Arctic.

Cornell University, Ithaca, N. Y.

The leather industry of Germany is one of the most important of German industries, and may be said to occupy the third to fourth place, if all its branches are taken into account, and it is one that is daily expanding in every direction. According to the census of July 14, 1895, the number of persons engaged in it was 599,717, of whom 433,586 were occupied in the boot and shoe trade, 74,809 in making saddlery, harness, etc., 47,480 in tanning, and 16,218 in the glove trade. The commerce in hides and skins is immense and is one of the leading branches of trade, as is also that of tanning materials. In 1895 the value of the former imported was £7,297,700, and that of the exportation amounted to £2,579,050. Besides this, £1,549,300 worth of tanning materials were brought into the country. The exports of worked-up hides, leather, and "Wachstuch" (wax cloth) were valued at £4,925,450, and those of leather, harness, and pocket articles at £1,914,350.

The first vessel to be lighted by acetylene gas is the yacht White Queen, recently launched by Messrs. J. Duthie, Sons & Company, of Aberdeen, for Mr. J. Gordon Stewart, of Essex. She is 102 ft. over all, 18 ft. beam, 18 ft. depth of hold, and 190 tons gross register.

THREE PHASE MOTOR AT BELLEGARDE.

AT Bellegarde, twenty miles below Geneva, the power of the Rhone is utilized for driving many different plants, partly by means of ropes, but mainly by electrical transmission. The most interesting of the works driven electrically at Bellegarde is the cotton mill recently erected. This mill, which is 550 yards distant from the water power and generators, employs one three phase motor of 120 to 170 horse power for driving the openers, carding, combing and drawing frames and fliers, and supplies 300 incandescent lamps. One 120 to 170 horse power three phase motor drives the self-actors, and one 15 to 30 horse power motor of the same class is employed for driving the ventilating fans and the workshops.

These motors, which were constructed by Brown, Boveri & Company, Baden, are illustrated in the annexed engravings, which we take from Engineering. The larger motors weigh 5·8 tons each and the smaller motor weighs 1·2 tons. These motors are started by resistance starters, and under normal conditions attain their full speed in the space of one minute. The inducing part of the field of the motor which connects with the mains is outside, and stationary, while the armature or induced part is made rotary, thus avoiding sliding contacts. The winding of both parts is similar, the core being composed of alternating laminæ of sheet iron and insulating paper pressed together between two outer rings and pierced near the periphery by equidistant oval-shaped (or circular) holes in which the windings are placed. Portions of the inducing winding are so bent and arranged as to be always at the same distance from the axis of the motor, and in large motors (from 40 to 120 horse power) the straight portions are placed in stiff paper or ebonite insulating tubes fitting into the oval perforations.

The winding of the induced rotary part consists either of wire or of copper bars, and is also placed in peripheral holes. By this construction all the magnetic resistances in both parts are reduced to a minimum, while the peculiar winding of the inducing part insures perfect symmetry, great economy of space, and easy inspection and repair. The wires or bars of the rotary part extend beyond the core on each side, the ends being bent and soldered together to form a drum winding short circuited on itself. The windings of both parts are symmetrical, but independent of each other as regards polarity, the peripheral holes being equidistant and the surfaces of the alternating iron cores being smooth and uniform all around, and any number of poles can be formed in the inducing part without any polar projections. By virtue of this arrangement, the motor is enabled not only to run non-synchronously with the generator, but with a considerable torque without separate excitation, so that commutators and brushes are entirely dispensed with.

To start these motors it is necessary to produce a difference of phase to destroy the equilibrium of forces, which, although the current be switched on,

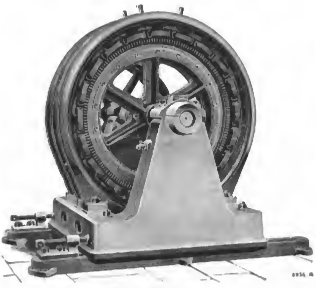

FIG. 2.—SIDE VIEW.

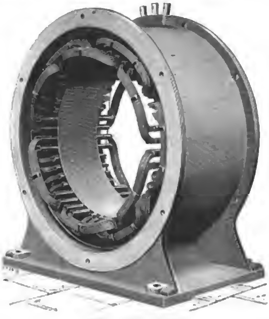

FIG. 3.—FIELD MAGNET.

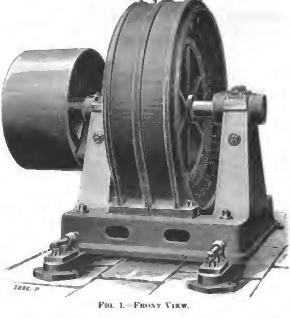

FIG. 1.—FRONT VIEW.

FIG. 4.—ARMATURE.

THREE PHASE MOTOR USED IN THE BELLEGARDE COTTON MILL ON THE RHONE.

causes the induced part to remain neutral, and prevents it from rotating unless it is set in motion. As differences of phase are produced by differences of self-induction, the desired object is brought about by adding to the ordinary winding of the motor a starting winding of small cross section having a different self-induction, so that when the two are placed in circuit with a generating alternator, a difference of phase and hence a rotary field is set up, which overcomes the neutral state and causes the armature to rotate.

The efficiency of these motors increases with the size and varies from 70 to 90 per cent. They are capable of developing 50 to 100 per cent. more than their normal power, and require no attendance beyond the renewal of oil once a week.

THE USE OF TURBINES WITH A HORIZONTAL SHAFT FOR RUNNING DYNAMOS.

IN recent years the applications of electricity have greatly extended, and this has very naturally led engineers to have recourse to the numerous waterfalls distributed over the face of the land for putting them to profit. In the first installations of this kind they confined themselves to the use of such motors as were then employed—waterwheels of all kinds, parallel turbines with vertical shaft, etc. These primitive apparatus, however, necessitated complicated arrangements, often cost considerable to keep them in repair, and were liable to give rise to serious accidents that sometimes occasioned a lengthy cessation of work. On another hand, it is well known that, contrary to what occurs with steam engines, the greater part of the expense connected with works run with water power resides in the cost of installation, the expense of maintenance and of running the machines being reduced to a minimum. It will be seen how advantageous it is from a technical as well as an economic view point to diminish the cost of installation as much as possible, while at the same time simplifying and improving the motors in such a way as to increase their performance.

It is to this end that have been directed the studies of hydraulic engineers, who have thus been led to the devising of special turbines designed more particularly for the running of dynamos. Among the numerous models of this kind we may mention the turbines with horizontal shaft which actuate dynamos directly without the intermedium of any transmission, and which were devised by the Brault, Teisset & Gillet establishment, founded by Mr. Fontaine, the inventor of the turbine that bears his name. These turbines are now very widely distributed, and we are going to describe a few types of them selected from among some of the more important installations.

The keying of the armature upon the same shaft, or upon a shaft forming a prolongation of that of the motor, is evidently one of the simplest and most rational of matters; but, unfortunately, such an arrangement is applicable only to falls of a height greater than 13 ft., since, below this figure, the velocity of the turbine is generally too feeble, especially when of a certain power.

On the contrary, with falls of from 25 to 40 ft. such an arrangement becomes very easy, and in this case the simplest application consists in employing (in placing it horizontally) the new American mixed centripetal turbine that we have already described in this journal. The turbine is installed in the same room with the dynamo, and then operates in an iron plate tank placed above the down stream level.

Figs. 1 and 2 show the installation of such a turbine. A frame of T iron, or, what is preferable, of cast iron, receives the tank, to one of the sides of which is fixed the discharge tube that enters the down stream water. The shaft of the turbine rests upon two self-lubricating bearings of considerable length, and, moreover, in order to prevent any loss of water in its exit from the tank, it passes through two stuffing boxes mounted upon the latter.

The opening and closing of the turbine is obtained very easily by means of a small handwheel carrying internally a fixed nut through which passes the threaded shaft that actuates the cut-off. This shaft likewise traverses a stuffing box at its exit from the tank. The jacket of the turbine in the interior of the tank is very strong, and a manhole gives access to the motor, so that it can be easily cleaned when necessity requires it.

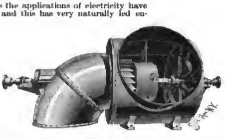

FIG. 1.—MIXED CENTRIPETAL TURBINE WITH HORIZONTAL SHAFT.

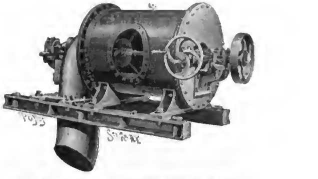

FIG. 2.—MIXED CENTRIPETAL TURBINE OF 45 H. P.

The following are the principal dimensions, etc., of the turbine represented in Fig. 2:

Motor	40 to 45 h. p.
Fall	42 ft.
Discharge	90 gallons
Velocity	630 revolutions
Diameter of delivery pipe	28 in.
Diameter of tank	3·5 ft.
Length of tank	4 "
Diameter of discharge pipe	20 in.
External diameter of distributer	20 "
Height of buckets	6 "
Diameter of turbine	13 "
Diameter of turbine shaft	2·4 "
Diameter of turbine shaft at bearings	2·4 "
Width of bearings	4 to 5·5 in.
Distance between bearings	8 ft.

The performance of these turbines varies between 80 and 87 per cent. of the total theoretical power. They are therefore excellent motors, which combine extreme simplicity with very great stability. Moreover, in most cases, in order to obtain a still better result, the dynamo and motor are mounted upon the same frame, which is cast in a single piece.

But, in the case of large falls and heavy discharges such turbines, since they are not balanced, may give rise to lateral thrusts upon the shaft. In order to remedy this inconvenience, the manufacturers have conceived the idea of keying two horizontal shaft turbines of opposite direction upon the same shaft. Fig. 3 represents a turbine established upon this principle.

This new type of turbine was devised a few years ago by the Brault, Teisset & Gillet establishment for application in a very special case. It was a question of running a sugar cane mill that had to be actuated by a reversible hydraulic motor that, when necessity required it, could be run backward in order to clear the mill when the cylinders became gorged and choked up by an excess of bagasse.

As this arrangement furnished good results, the manufacturers naturally thought of applying it to the direct running of dynamos. Fig. 3 represents a turbine of this kind designed to run the Bourganeuf works for transmitting electric power. The motor is established upon a solid cast iron frame which carries both the tank that holds the two turbines and the dynamos that they actuate. The tank is closed laterally by the two distributers of the turbines, which carry a central tubulure that permits of connecting them with each other by means of a cast iron tube that serves likewise as a cross brace, and thus permits of avoiding flexions due to pressure.

The orifices of these two distributers extend only over half of their circumference, and their opening and closing are regulated by means of bronze clack valves rendered absolutely tight through an ingenious arrangement of small grooves formed upon the surfaces in contact. The clacks of the two opposite distributers are connected with each other by means of steel rods and powerful springs which permit of balancing the pressure of the water in great part, and, consequently, require but a very feeble stress for their maneuvering. Moreover, they are very easily controlled by means of a handwheel mounted upon a shaft that carries pinions which engage with the rack that actuates them. This shaft alone is provided with a stuffing box.

The two turbines are of cast iron and hooped with steel. They are keyed outside of the tank upon the driving shaft that traverses the tube which connects the two distributers. This arrangement permits of dispensing with the use of stuffing boxes. As for the steel driving shaft, that is prolonged upon the external face of each turbine, traverses each of the two discharge tubulures through a stuffing box and rests upon two wide pillow blocks, each provided with three lubricating rings. At one of its extremities this shaft carries one of the halves of a coupling box that serves to unite it with the shaft of the dynamo that is placed in a line with it. The pillow blocks are mounted upon strong uprights cast in a piece with the frame.

The turbines are parallel reacting ones, each motor, running two turbines, furnishes 225 h. p. with a discharge of 213 gallons, and a fall of 95 feet, and with a velocity of 400 revolutions a minute.

The following are the principal dimensions of these machines:

Diameter of the tank	3·5 ft.
Length	3·75 "
Mean diameter of distributer	25 in.
Number of effective orifices distributed in two equal sectors to the right and left of the vertical shaft	14
Height of orifices	0·75 in.
Width " "	4 "
Mean diameter of turbine	25 "
Number of orifices	20
Width of "	5 "
Height of buckets	6·5 "
Number of revolutions	400
Diameter of steel shaft	5·25 "
" at the pillow blocks	4 "
Width of the " "	7·25 "

These motors, which have been run for two years, have given excellent results, and their operation, which is very regular, has never caused any heating. So it seems that the use of them is indicated in cases when it is desired to utilize falls of large discharge, and to obtain relatively feeble velocities of from 400 to 600 revolutions a minute for directly actuating dynamos, since, under such falls, centripetal turbines would give too high velocities that would necessitate the use of intermediate transmissions.

There is still another case in which centripetal turbines cannot be employed, and that is when it is desired to obtain these same velocities of 400 or 600 revolutions

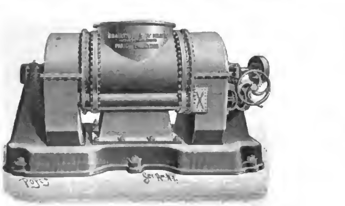

FIG. 3.—MIXED CENTRIPETAL BALANCED TURBINE.

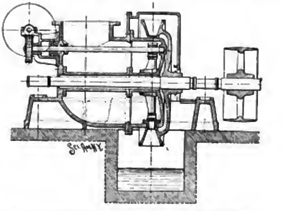

FIG. 4.—CENTRIFUGAL TURBINE WITH HORIZONTAL AXIS AND OF 100 H. P.

with a very feeble discharge and a very large fall. In this case it is possible to employ either Pelton wheels or a centrifugal turbine, a few of the types of which we are going to study.

Fig. 4 represents a turbine capable of furnishing from 30 to 60 h. p. with a fall of 325 ft. and a velocity of 700 revolutions a minute. This motor consists of a delivery pipe forming a frame and connected with the distributer. This latter carries a tubulure that is connected with the elbow of the pipe, thus crossbracing these two points and preventing any flexion of the distributer, which, at its lower part, is provided with a certain number of orifices, the size of which is calculated according to the discharge, and the opening and closing of which are regulated by means of a circular cut-off. This latter revolves around the central tubulure, and the maneuvering of it is effected by means of a handwheel, which, through the intermedium of an endless screw, actuates the shaft that carries the pinion which gears with the rack of the cut-off.

The turbine is keyed upon a steel shaft that rests upon two pillow blocks that are mounted upon a solid cast iron frame which surrounds the turbine. A cast iron tank prevents the water from overflowing in the room.

The principal dimensions of this turbine are as follows:

Mean diameter of distributer.....	27 in.
Width of orifices	1·6 "
Height	0·4 "
Number..........	5
Mean diameter of turbine.......	28 in.
Number of orifices	44
Number of revolutions.....	700
Discharge of turbine....	15 gallons.
Height of fall	328 ft.
Power of turbine	30 to 60 h. p.
Diameter of shaft	3·6 in.
" " " in bearings ...	2·8 "
Width " " " " ...	5·5 "

If the discharge of the fall is still less, the delivery pipe will naturally have a much smaller diameter. In this case it is possible to adopt the arrangement shown in Fig. 5, that is to say, to cause the shaft of the turbine to pass over the delivery pipe. The distributer is then reduced to a truncated sector forming a continuation of this pipe and carrying the orifices necessary for the admission of the water as well as space for the cut-off. This latter is thus asymmetrical with respect to the vertical plane passing through the shaft of the motor. As for the rest of the installation, that is like that of the one described above. Two turbines of this type have been applied to the running, through belts, of the dynamos used for the lighting of the city of Fort-de-France, Martinique.

The following are the essential characteristics of them:

Mean diameter of distributer....	36 in.
Width of orifices	1·2 "
Height.	1 "
Number	6
Mean diameter of turbine	3·6 in.
Width of orifices	2 "
Number "	36
" of revolutions	400
Discharge of the turbine	25 gallons.
Height of fall	160 ft.
Power of turbine	40 h. p.
Diameter of shaft	3·2 in.
" " " in bearings.....	2·2 to 2·4 in.
Width " " "	6 and 5 "

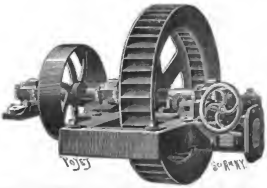

FIG. 6.—CENTRIFUGAL TURBINE WITH HORIZONTAL AXIS AND PARTIAL DISTRIBUTER.

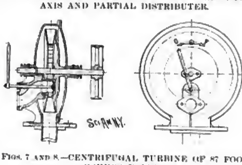

FIGS. 7 AND 8.—CENTRIFUGAL TURBINE OF 87 FOOT POUNDS POWER.

Fig. 6 represents another turbine of the same type established for a still smaller discharge.

Finally, we shall give a description of a turbine of exceedingly small size, established on the same principle as the preceding, and designed to furnish but a little power when, for example, it is desired to use the pressure of city water mains for domestic purposes. These small motors, which may be employed for running dynamos, elevators, sewing machines, dumbwaiters, etc., are much used in foreign countries. The turbine is set in operation by means of a simple lever connected with the cut-off that acts upon the distributer. The

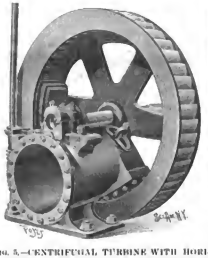

FIG. 5.—CENTRIFUGAL TURBINE WITH HORIZONTAL AXIS AND PARTIAL DISTRIBUTER (40 H. P.)

entire turbine is placed in the interior of a cast iron tank which is absolutely tight. The water is discharged at the bottom through a pipe that may be bolted under the base of the turbine.

The principal dimensions of the type represented in Figs. 7 and 8 are as follows:

Mean diameter of distributer .	8 in.
Number of orifices...	1
Width of orifice.......... ...	0·32 "
Diameter of turbine..........	8 "
Number of orifices......	26
Width..........	0·75 in.
Diameter of delivery pipe.....	1·6 "
Height of fall	160 ft.
Discharge of turbine..........	1 pint
Power	87 ft. pounds
Diameter of driving shaft....	0·75 in.
Number of revolutions.......1,375	

In this general study we have confined ourselves to an examination of motors designed for the utilization of high falls, but intend to complete the subject some time in the future by a description of turbines utilizing a low or medium fall of water.—Le Genie Civil.

Reports from the Wilcannia district of Australia state that the drought is being severely felt there. On some stations very heavy losses of stock have already occurred. On one holding alone the manager estimated that the sheep were dying at the rate of 1,000 a day. Within a radius of 100 miles of Wilcannia the country has the appearance of a desert. Right through to Wentworth, a distance of 200 miles down the river Darling, there is not a vestige of feed to be seen, while the seventy mile track toward Hay is in an equally deplorable state. Up the river toward Bourke there is no feed until Windbar is reached, a distance of 120 miles from Wilcannia. In the Menindie district also grave fears are expressed as to the result of the prolonged drought. At the end of last year there was only 867,800 sheep in the district, being a decrease from the previous year of 90,960. The loss since 1883, which has been at the rate of 100,000 per annum, is almost entirely due to bad seasons.

THE ACCOMPLISHED UTILIZATION OF NIAGARA.*

IN response to your request for succinct data as to the net result of the enterprise at Niagara, in regard to which the Electrical Engineer has made so full a record during the past six years, I am glad to be able to submit figures of a remarkably encouraging character. The project has never promised so well as now, either in practical operations or in those financial results which, as Mr. Brunel insisted, can alone justify even the greatest engineering plan.

Since work was begun in 1890, we have had at least four financial crises, and other influences, deterring the establishment of new industries requiring power. Considering these general and well-known adverse conditions, coincident almost with its life, the wonder is that this company has steadily progressed, and, as above indicated, has virtually reached the point of self-support. Under such conditions, and in view of the necessarily experimental character of the work, it would have been folly at any earlier date to seek to provide for an installation larger than necessary to demonstrate that this enterprise can accomplish real work and promise real profits.

The plans of the Cataract Construction Company and the works of the Niagara Falls Power Company are so far completed that delivery of power to customers in Buffalo has been successfully instituted, and the calls for power under contracts actually executed (and in excess of the present capacity of the works) will provide annual rentals which, with contracts in negotiation, represent a total income from that source falling not far below half a million dollars.

The present electrical installation comprises three dynamos, each of 5,000 electrical horse power, of which one should be kept as a reserve; but the demand has made such reservation impossible, and the contracts already made for 15,825 electrical horse power exceed not only the prudent, but the actual, capacity of these works, which require immediate extension, with every prospect of prompt and profitable employment.

The proposed extension involves doubling the present capacity of the transmission line to Buffalo which, already in successful operation, is delivering 1,000 electrical horse power; the extension of the wheel pit for its full length, so as to have capacity in all for ten 5,000 horse power turbines and dynamos; the installation of seven 5,000 horse power turbines and dynamos, in addition to the three now in operation; and the extension of the power house to cover the new installation. The work of such an extension of the wheel pit is about one-third completed; the right of way from Niagara Falls to Buffalo is complete; the pole line already erected has a pole and cross arm capacity for 20,000 electrical horse power, with copper conductors in place for 5,000 electrical horse power. Upon definite proposals already received, the entire installation above described can be accomplished within the year 1897.

As a concrete presentation of the facts, I will add a list of the contracts for power up to election day, 1896. No more eloquent statement as to results achieved could be given if I were to fill a volume of your journal:

It will be obvious, at a glance, that Niagara has already started on its career as a great chemical center, and thus justifies the predictions that the chemical trades would center ultimately around the sources of cheap power in large quantity.

* By W. B. Rankine, Secretary Niagara Power Company, in the Electrical Engineer.

EXPRESS COMPOUND LOCOMOTIVE WITH AUXILIARY GEAR.

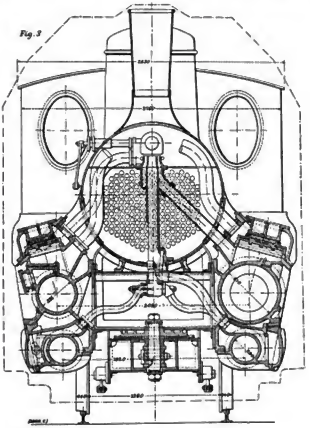
IN designing the compound locomotive with a single pair of driving wheels, which is shown in the accompanying engravings, the constructors, Messrs. Krauss & Company, of Munich and Linz, aimed at combining the chief advantages of uncoupled wheels with the greater traction force which four coupled engines afford in starting and in mounting gradients, while further they desired to secure a more perfect adaptability of the engine to the various requirements concerning speed and power that arise during ordinary working conditions. Very large cylinders, quite desirable in cases of great power being required at low speed, give unfavorable results at high speeds. If the customary two cylinders are to be adhered to, it is hence necessary to keep down their dimensions. The design adopted by Messrs. Krauss & Company enables them to adapt the dimensions of the cylinders to the conditions obtaining at high speed, while for low speeds they bring into use an auxiliary engine; thus they double their tractive power when needed and can exert a great pull with early cutoff.

It is owing to the willingness on the part of the directors of the Bavarian State Railway, and particularly of the chief of the engine department, Oberregierungsrath Mahla, to test an entirely new arrangement, that this idea has been carried into execution. Having ordered twelve engines of the standard four coupled express type, Class B XI (cylinders 17·52 in. and 26·38 in., 24 in. stroke, 73·2 in. driving wheels, and a steam pressure of 13 atmospheres), the directors conceded that one of these engines should be built on this new plan, provided the construction was such that the locomotive could, in case of failure, be converted so as to fairly resemble a standard engine.

The locomotive herewith illustrated, known as No. 1400, is the only one of its kind. It was delivered in December, 1895, was on regular duty during the months January to March, 1896, was then sent to the Bavarian Exhibition at Nuremberg, and since October, 1896, has been again in uninterrupted service.

Our illustrations clearly bring out the chief constructive peculiarities. Apart from the rear axle, which has its bearings in a short outside frame, the main framing is internal; the cylinders of both systems, as well as their gears and valve chests, lie outside. In accordance with the conditions of easy convertibility, the chief parts are like those of Class B XI. The boilers, e. g., are identical—not reckoning slight changes in the smokebox, necessitated by the alteration in the pipes—and so also are the complete bogie (of the type designed by Mr. James Stirling, Southeastern Railway), and the driving wheels, for which latter the designers would have preferred a larger diameter. Above the rear axle, the main framing is provided with sectors in order to admit of the eventual addition of horn plates for the reception of the axle boxes of a coupled axle, should the present construction not be ultimately approved of.

The main pair of cylinders drive the 73·2 in. wheels; the dimensions of the cylinders are smaller than those of the B class, the diameter of the right hand side high pressure cylinder being 15·16 in. and that of the left hand side low pressure cylinder 24·01 in. The stroke in both cases is 24 in. The cylinders are inclined 6 in 100,



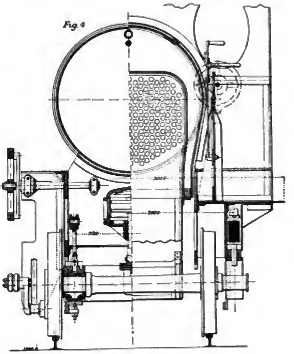


FIG. 5.

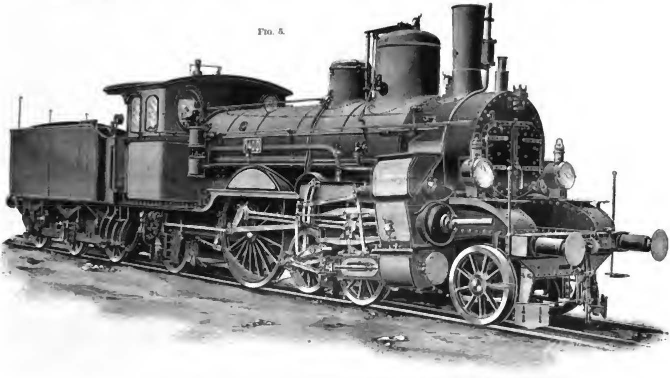


COMPOUND LOCOMOTIVE, WITH AUXILIARY CYLINDERS, FOR THE BAVARIAN STATE RAILWAYS.

because the auxiliary cylinders had to be placed underneath, not to interfere with the engine profile. The valve chests, which are fitted with American balance slide valves, also lie inclined, in both the longitudinal and transverse directions. The valve gear is of the Heusinger-Walschaert type. The cutoffs are the same on both sides, while the cylinder ratio is 1 : 2·51.

The receiver pipe passes through the smokebox, and bears above a safety valve loaded to 5·5 atmospheres, and in front a Ricour air suction valve. The exhaust into the chimney takes place through an annular pipe. The starting gear consists of a Lindner cock, which is connected with the reversing rod, and at full gear allows the steam to pass from the boiler to the receiver, and of a Krauss interruption slide, which, fixed outside the high pressure cylinder and worked from the right hand link, prevents the passing of steam at those positions of the crank when the pressure in the receiver would only impede the starting.

The auxiliary engine is intended to insure a reliable and powerful start. It is entirely independent of the main engine, and is fitted, as shown in the engravings, with two equal sized cylinders. It is not in use except when a heavy pull is needed, that is, in starting, and on steep gradients. Under ordinary conditions, the auxiliary engine is not switched in, so to say, and its wheels are kept off the rails and remain stationary. Having regard to the low speed at which the auxiliary driving wheels are to run, and to the circumstance that the weight and bulk of the auxiliary gear should be as small as possible, these auxiliary wheels have been made the same diameter as the trailing wheels, namely, 1 meter (39·3 in.)

The auxiliary driving axle has its bearings in horn plates which are formed by plates riveted to both sides of the main frame. This axle has not any ordinary bearing springs, but is connected with the springs of the main driving axle in such a way that these springs tend to lift the auxiliary axle from the rails and press its bearings against the upper stops. Normally, therefore, the auxiliary driving wheels remain 30 millimeters (1·2 in.) above the rails.

When the auxiliary engine is to perform its duty, the auxiliary driving axle is depressed by the action of the piston of a vertical steam cylinder of 412 millimeters (16·2 in.) diameter, fixed above its center, as shown in Fig. 7. The piston with its ball socket joint and bronze footstep bears against a cast steel support, fixed between two plates which connect the bearings. Steam is admitted through a threeway cock, which is seen on the right hand side of the dome in the perspective view, Fig. 5; at the same point is also a lubricator for the piston. The steam pipe to the cylinder passes under the lagging of the boiler, lest the pipe freeze. An automatic valve in the gear cylinder takes the condensed water down into the ashbox. The steam which is discharged on releasing the shaft was originally permitted to escape as it liked; later on a special pipe was added which conveys this steam into the chimney, in order to avoid soiling the engine by the oil in the steam.

The levers between the auxiliary axle bearings and the bearing springs of the main driving axle serve the further object of equilibrating the load when the auxiliary axle is lowered, in such a way that the load is distributed over the running wheels. When the auxiliary wheels are pressed down, the whole engine is raised about 1 in. on the springs; at the same time, however, the front links of these springs are depressed by about 2 in., so that the deflection of the springs, and consequently the load upon them, remain unchanged. The springs are hence slightly inclined under both conditions. When the auxiliary axle is lowered, their front extremity lies a little lower, when the axle is suspended, a little higher than the other extremity. The forces entering into play are as follows: When the auxiliary motor is out of use, the weight available for adhesion consists of the dead weight of the main driving wheels and their attachments, amounting to 3·73 tons, plus the load on the driving springs amounting to 11·12 tons, making a total of 14·85 tons. When the auxiliary axle is pressed down, however, the following additional adhesion weight becomes available:

	Tons.
Deadweight of auxiliary axle and its attachments	2·130
Pressure on piston of loading cylinder	17·330
	19·460
Less upward pressure exerted at the point, B, by the levers connected to the driving springs	4·635
Additional adhesion weight	14·825

It will thus be seen that the adhesion weight amounts to 29·67 tons when the auxiliary axle is being used, and to 14·85 tons in the other case.

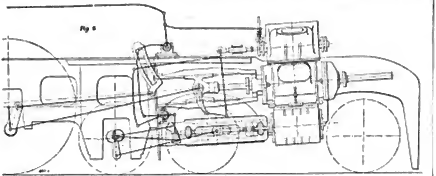
The cylinders of the auxiliary engine, which have a diameter of 290 millimeters (11·4 in.) and stroke of 460 millimeters (18·1 in.), are bolted to the lower side of the large cylinders; their valve chests lie horizontally and point outward. The arrangement is clearly shown by Figs. 3 and 6.

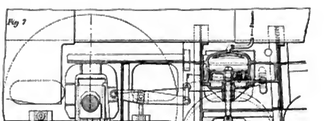
The working gear is shown by Figs. 5 and 6. From these views it will be seen that the crossheads and guides of the auxiliary motor are inclosed within a metallic case, lest dust and dirt from the hind bogie wheels should injure them. The valve gears of both engines are actuated from the same shaft, and are permanently connected in such a manner that during forward motion, which corresponds to equal performances by both engines, the large engine works with a later cutoff. For this purpose the length of the suspension link is such that when the expansion blocks of the large engine are at midgear, those of the small engine are somewhat below this point; a cutoff at 0·4 in the case of the former corresponds to a cutoff of 0·17 in that of the latter. The small engine is fitted with Stauffer grease cups, which are economical and sufficient for the short periods during which this auxiliary engine has to run. For the purpose of lubricating the piston and slide valve, condensation apparatus has been provided which feeds only as long as the engine is under steam.

The regulator slide of the auxiliary engine is put in the smokebox, in the steam pipe of the large engine. As a result the small engine receives steam only when both regulators are open. The rod actuating the auxiliary regulator passes laterally out of the smokebox, and is manipulated by a special handle from the driver's footplate. In order to render impossible any mistakes on the part of the driver, such as giving steam to the auxiliary axle before putting it under load, or releasing it again before shutting off steam, the regulator handle and the shaft which actuate the threeway cock have been made mutually interlocking.

As regards other special features of the locomotive, the mechanical sandbox should be mentioned. In the locomotive as originally constructed steam sanding apparatus was used. But the steam device froze during winter—the Bavarian lines are exposed to exceedingly cold weather—while the mechanical device since adopted has always answered during severe frost. The sand is fed from the box by a screw conveyor with left and right handed thread; the screw is actuated from the right hand link of the main engine in the way we shall explain presently. Above the small gear wheels the sand pipe branches and contains a clack valve, which is controlled by the pull on the threeway cock; thus the sand is strewn in front of either the auxiliary driving wheels, when they are lowered, or of the large driving wheels. As long as the block is at the center of the link, the apparatus will manifestly be at rest.

In most respects the engine under notice is of the usual construction. It is fitted with a Westinghouse brake (which acts upon the driving and the smaller hind wheels), with Petri's recording speed meter, actuated from the right hand eccentric of the main engine, with Körting's safety injectors, with Nathan lubricators for the main cylinders, and with the requisite apparatus for steam heating the train. The locomotive being somewhat longer than those of the standard type, but requiring less water, the limited length of the turntables has caused no difficulties. A small three axled tender carrying 13·7 cubic meters (481 cubic feet) of water has proved amply sufficient; the new standard engines have four axled tenders on two bogies and carry 18 cubic meters (636 cubic feet) of water. The chief dimensions are:





COMPOUND LOCOMOTIVE, WITH AUXILIARY CYLINDERS, FOR THE BAVARIAN STATE RAILWAYS.

Boiler:

Grate, length	2181 mm. (85·8 in.)
" width, front	1021 " (47 ")
" " aft	991 " (39 ")
Grate area	2·2 m.² (23·7 sq. ft.)
Mean diameter of boiler shell	1400 mm. (55·1 in.)
Thickness of shell plates of boiler barrel	15·5 " (0·61 ")
Height of center line of boiler above rails	2275 " (89·5 ")
Number of tubes	236
Diameter of tubes, outside	45·5 " (1·79 ")
" " inside	41·0 " (1·61 ")
Length between tube-plates	3780 " (148·8 in.)
Heating surface of fire-box, outside	9·9 m.² (106·6 sq. ft.)
Heating surface of tubes, outside	122·1 " (1314 ")
Total heating surface	132·0 " (1421 ")
Steam pressure	13 atm.

Main Engine:

Cylinder diameter, high pressure	385 mm. (15·16 in.)
Cylinder diameter, low pressure	610 " (24·01 ")
Cylinder ratio	1 : 2·51
Stroke	610 mm. (24·01 in.)

" coal	5·0
" fittings	0·5
" fully equipped	34·2

The brake has twelve blocks and acts upon all the wheels.

The above figures show that the total pull of the locomotive is 2 × 3,290 kilogrammes = 14,462 lb. = 6½ tons, which is a high value. In order to facilitate a comparison with English engines, Messrs. Krauss & Company assume a steam pressure of 190 lb. and driving wheels 7 ft. in diameter: they would require cylinders of 26·5 in. diameter, which would not be acceptable for high speed locomotives.

We have already mentioned that the locomotive was first put to regular duty during the months January to March, 1896. This was on the lines Munich-Ulm, Treuchtlingen, Regensburg, Simbach, Salzburg, Kufstein, Kempten. Objections had previously been raised that the auxiliary engine could not be thrown in without a jerk, and that its steam pipes would, owing to their use for short periods after long intervals, be exposed to freezing. Both objections have proved unjustified. The throwing in of the auxiliary engine has taken place when the locomotive was running at speeds up to 75 kilometers, 46·6 miles. The operation was so smooth that persons standing on the engine and not watching the driver did not notice the change over. It has, moreover, been found that the switching in will rarely be required while the locomotive is in motion. It soon became apparent that the help of the small engine was needed over short distances only. It had been calculated that the auxiliary engine would have to help, not only in every start, but at every gra-

* Messrs. Krauss & Company base the pull of compound engines upon the high pressure cylinder, and reckon only 52 per cent. of simple expansion.

dient of 1 : 200 or more for a distance of about 2 kilometers, 1¼ miles. Under this supposition, the locomotive would, on its regular trip, have had to do about 15 per cent. of duplex working. As a matter of fact, it has resulted that the large engine takes trains of 180 tons alone over gradients of 1 : 100. There is only one long gradient of 1 : 100 and 1 : 94 between Freilassing and Traunstein, on the Salzburg line, where the assistance of the auxiliary engine is required over a distance of 12 miles. Trains of 200 tons are to ascend at a speed of 31 miles (50 kilometers) on this gradient. Otherwise the use of the auxiliary plant is limited to starting and getting up speed after slow runs, and on the whole the duplex working is confined to 5 per cent. of the total track length. During the official tests which took place in March last, the engine hauled a train of 183 tons over a long gradient of 1 : 300 and 1 : 400 with a speed of 54 miles per hour; on a gradient of 1 : 55, between Miesbach and Schliersee, a speed of 30 kilometers (18·6 miles) was realized. In that case, of course, with the assistance of the auxiliary engine. Snow and ice have as yet not caused any trouble, although severe snow storms, followed by extreme cold and heavy drifts, have been experienced.

The complicated construction and the large number of axles have been commented upon adversely. With regard to the former point, it may be said that the four-cylinder engines of Mallet & De Glehn, whose right of existence nobody questions now, are certainly not any simpler. A four-coupled engine of the latter type has, on the contrary, two more coupling rods and four more bearings, and the secondary mechanism is essentially more bulky than the auxiliary engine. It is further to be considered that De Glehn's secondary mechanism is always running, which means additional friction, oil and repair. With the auxiliary engine under notice, which is idle for 95 per cent. of the run, those additional expenses come in to the amount of 5 per cent. only. There is a further advantage as compared with compound locomotives fitted with change-over gear, in being able to work with fresh steam in both engines. Such locomotives have to resort to strong throttling, and hence to waste steam, while the main and the auxiliary engines of Messrs. Krauss & Company work with full boiler pressure.

As concerns the second point, the locomotive has exactly as many driving and carrying axles as the "American Atlantic" type, which is more and more coming to the front. Together with its three-axled tender, it has not any more axles than the normal "American" class, with its four-axled tender.

The external appearance will probably not please in England, since the locomotive is built on the German "everything outside" style. It must be granted that the two separate and entirely different gears make the engine look somewhat complicated, to which appearance one has first to accustom oneself. But this might be altered. It is manifest that four-coupled locomotives could be provided with this auxiliary gear. Such engines might rival the six-coupled locomotives of the American ten-wheel class. We are indebted for cuts and particulars to Engineering.

OXYGEN, FRESH AIR AND HEALTH.*

ALL biologists agree that oxygen is the prevailing essence of the body; is the most important agency and is the chief element in the health of man.

The world is seven-tenths oxygen. The great oceans are three-fourths and the water we drink is two-thirds oxygen.

The solid matter of the earth is over sixty per cent. oxygen by weight and ninety per cent. in bulk. If a man weighs 150 pounds, 110 is oxygen, and if the oxygen were set free, it would fill 750 cubic feet of space.

What we call fire is but the dangerous activity of oxygen. The flame you see is but the union of carbon with oxygen. Oxygen is all activity; its mission is to change; it tears down only to rebuild; if it destroys by fire, it saves all the materials and quickly uses them to rebuild something else. It is the great builder of the animal kingdom and is man's greatest friend, for it destroys the bad parts of the living tissues and builds good in its place.

Oxygen may become dead if confined in a close room; that is why we notice that dead smell in rooms that have been closed for any length of time.

Sunlight also has much to do in keeping air in a healthy condition. No plant can grow in the dark, neither can man remain healthy in the dark, ill ventilated room. When the first blind asylum was erected in this State (Mass.), the committee decided to save expense by not having any windows. They reasoned, very logically, as the patients could not see, there was no need of any light. It was built without windows, but ventilation was well provided for, and the poor sightless patients were settled in the house. But things did not go well; one after another began to sicken and great languor fell upon them; they felt distressed and restless, craving for something they hardly knew what. After two had died and all were ill, the committee decided to open the windows. The sun poured in and the white faces recovered their color; their flagging energies and depressed spirits revived, and health was restored. Is this not a good illustration of the necessity of sunlight in the animal economy?

Take an illustration of the necessity of oxygen in water, which I have told you is of itself two-thirds oxygen in composition. Let it stand in a room any length of time, it becomes insipid; the oxygen entrapped between its particles has become dead or lost. Take fishes and put them in a limited quantity of water and they soon die. Why? All healthy water has oxygen entrapped between its particles. The gills of the fish are its lungs, and they take water into their mouths and force it back through their gills and thus take out the oxygen, the same as is done in our lungs; and as soon as this is all consumed, they die, just as we would do if we breathed carbonic acid gas.

Small bodies of water become slimy and covered with what some call "frog pond," but frogs have nothing to do with it, for if you confine rain water in hot weather, the same thing will occur. There is no water so pure as that you see in the little rivulet dashing over the rocks, as in that way a full supply of oxygen is entrapped between its particles. It is the same with large bodies of water thrown about by the wind. Air is only two-fifths oxygen, but without it there could be no fire. The greater the draught, the greater the fire. You all know that fire burns much better some days than others, from the fact that the barometer is higher, causing a greater pressure on a square foot of air, and is as 1,000 to 824 for moist easterly air, and that which we inhale contains thirty-six times more moisture than pure westerly breezes. If the air was pure oxygen, we should quickly burn up, and when a fire was once started it would finish up the building before the engine could reach it. Fire is the union of oxygen and carbon. You know the electric light has to have carbon.

A drop of blood contains the entire human body in miniature, in that it holds all the elements for a complete being. The blood carries carbon for the purpose of exciting the oxygen, and the air cells of the lungs bring it oxygen, just as the bellows will blow air upon the fire. The greater supply of air, the greater the draught and the more intensely the fire will burn. So life exists just in proportion as we breathe and exercise. In a good sized man there are three million of cells, one half air and the other half blood cells.

I have said that oxygen and carbon have a strong affinity for each other. At birth, at the first inspiration, the oxygen enters the air cells; a process called endosmosis takes place, whereby the oxygen passes into the blood cells, uniting with the carbon, forming carbonic acid gas, which in turn passes into the air cells (just as the rays of the sun pass through glass) and is breathed out.

Before the oxygen entered the blood cells the blood was full of carbon and dead matter. Carbonic acid gas is the union of oxygen and carbon. If the blood did not get any oxygen, it would not move out of the cells, but when uniting with oxygen it becomes red, vitalized, life giving blood and immediately starts on its mission through the arteries to every part of the system, there to undergo a change in the capillaries (which are hair like, hollow tubes), which convey the blood from the arteries to the veins. Here in the capillaries a burning process takes place, just as in the stove. Here the oxygen exchanges its life-giving properties for carbon. It builds and destroys.

Now if there is more carbon than oxygen, that is, if we do not breathe enough air, dead matter remains in the system because there is not enough oxygen to burn up all the carbon. Then there is dead matter left in the system which may cause disease of some organ. This burning is life. If you lift your arm or your little finger, it is necessary that some oxygen should burn up some carbon in order to set free the force necessary to move the muscle.

Fire and heat are simple expressions of force. The engine moves by force of the consuming oxygen and carbon. You burn when you exercise. The more exercise, the faster you burn, and more dead matter is thrown off, for this burning is life, and there is no other way of existing. Does this not show us that all animals should have some exercise in order to keep them in a healthy condition? We cannot live without burning, and we cannot burn without oxygen, which we only get in the air we breathe, and without it we could not exist three minutes. Were we obliged to rebreathe our own breath we should die in that length of time, as the air we exhale is full of poison. Life depends upon oxygen and must have it. Refuse it or stay in a room where the air is not changed, the blood stagnates, dead matter remains in the system, the muscles put on a tired feeling due solely to this cause, and is cured, not by medicine, but by natural oxygen alone. I say "natural," as chemists can produce oxygen, but it lacks Nature's vitality. When we do not have oxygen enough the heart acts feebly, the impulse of digestion is withdrawn, and the food may ferment in the stomach or pass out undigested and unused; the blood clogs the brain, the head begins to ache, the dead tissues through the body, instead of being carried off by the exhalations of the lungs and skin, are collected in every nook and corner, where they become a fertile soil in which the bacilli of tuberculosis thrive (as they enjoy just such soil), and are sure to make their nest; and colds, catarrh, and all other diseases of the air passages find good stamping ground.

All scientists say that oxygen carbonizes the tissues, and whenever carbon and oxygen meet, a fire ensues, as real as in the stove or furnace. This is what keeps the blood up to a much higher temperature than the hottest summer day. One great trouble with humankind is that we do not half breathe. A man weighing 150 pounds should have a lung capacity of twelve pints, while many persons only inhale from two to three pints at each inspiration; but singers inhale from seven to eight pints.

In a drop of blood there are one million corpuscles, and at each inhalation twenty millions are destroyed and their places are taken by new ones. The oxygen tears down all the worn out tissues. This dead matter is caught up by the blood and whirled back to the lungs, where it again meets oxygen, is purified and goes bounding back through the system.

One great cause of colds, catarrh, bronchitis and pneumonia is that the system has become weakened by being in hot, ill-ventilated rooms, not being supplied with enough oxygen to take care of all dead matter, and in this weakened state persons go out into cold air—a change of 60 or 70 degrees—and take cold, not from getting into the cold air, but by coming from overheated, sealed up rooms. If we were more in the habit of warming our blood in winter by taking brisk exercise "under the canopy," and less inclined to coddle ourselves up in nearly hermetically sealed rooms warmed with hot air furnaces with a tropical temperature, we should be a far healthier people. The presence of dead matter in the system is the cause of most diseases, and as oxygen is the greater factor in preventing them, I have thus emphasized its effect on the system.

I have said blood dies every second; that it loses its character of being blood; therefore, we conclude nutrition of the body consists of the white disks and the vitality in the red disks.

If, after eating pure food, fresh outdoor air is breathed, the blood will show a large increase in red corpuscles, but by drinking tea, coffee or other stimulants the red disks are decreased in serious proportions. Loss of sleep would do the same. Now before a cold is caught the white corpuscles must be diminished by weakness, preventing the blood from assimilating food. This being the case, we should let all stimulants alone, eat such food as will be readily assimilated to restore the white corpuscles and take a full supply of fresh air to transpose them into red disks. Colds should be looked after, as they often start their victims toward the grave, but no half breathing will do this. Nine-tenths of the human race do not half breathe, consequently the blood is not in a healthy condition; but full, deep inspirations many times a day, with perfect exhalations, will make the blood healthy and send a cold kiting.

Oxygen is indispensable in the food we swallow to insure perfect digestion. The teeth were made for a mill to grind the food, and during this process both oxygen and saliva are mixed with it. Persons who have lost their teeth or bolt their food are more liable to become dyspeptic from the lack of oxygen and saliva, as these are the most active promoters of digestion.

We often see pale, anemic young ladies; they need not be so if they would eat proper food and fill their lungs with fresh air, which is free to all. They live mostly on bread, sweetmeats and candy, food ill fitted to make white disks; consequently what little oxygen they get cannot make red disks, as there is not proper material by which nature can perform her duty. The system is full of dead soil, the person becomes debilitated and is a fit subject for tuberculosis germs to make lodgment in, for that is just the soil they like and in which one will produce over sixteen million in twenty-four hours, as they double every hour. Figure it up and see if I have the figures large enough.

There are two gallons of blood passing through the lungs every twenty-four hours, requiring more than three thousand gallons of pure air to change it from death to life giving blood. The colorless young ladies spoken of do not more than a quarter breathe; probably most of them do not inhale more than two or three pints of air at each inspiration, when it should be from six to eight to change the blood and rid the system of the dead matter which is clogging it.

If a person inhales enough fresh air and has disks enough to keep up a good fire, the bacilli tuberculosis will burn up, as they cannot stand such a fire. Fresh air is a germicide. To illustrate how quickly the air in a room may become impure, I will cite a school room examined in Boston. Two hours after the children had been in session there was found eighteen times more carbonic acid gas than there should be to keep them healthy. Many of you remember the black hole in Calcutta, where 146 prisoners were put into a close prison and only 23 were found alive in the morning, and most of those died of typhus fever in a short time. After the battle of Austerlitz 300 prisoners were placed in a prison and 260 died in a very short time. This shows us very clearly the effects of bad air on the animal economy.

A few words about consumption.

Bacilli germs make a lodgment in the lungs, and, like a besieging army around a city, every weak point is attacked, and the weaker the lung, the greater the predisposition to consumption. At night the rooms are shut tight to exclude all fresh air possible; they have on double windows and cotton stuffed in every crevice where it is thought there is a chance for fresh air to enter; then occupants feel weak in the morning and wonder how it is they take cold so easily. They think there must be something wrong about their system and consult the doctor. I have noticed that children who have bronchitis or pneumonia (especially among the poorer classes) are usually worse in the morning, when we should expect to find them better. Why? During the day, especially where there are children, the door is opened every few moments and in comes a gust of fresh air, but in the evening, as soon as they are in bed, the door is shut for the night, and this may be closed so that there is no chance for fresh air to enter the room of the sick child. Between the stove, mother and child all the oxygen is soon consumed. The child's lungs are so diseased that they can take in but little air, consequently need that of the purest kind, but this they cannot get in these close rooms, and many a parent has been made to mourn the loss of a dear child simply because she thought if it got a breath of fresh air it would take cold. It is the same with consumptives. When the cool weather comes they shut themselves up in hot, ill-ventilated rooms or go south, where the air is rarefied by heat, instead of taking exercise several times a day in open air and filling their lungs to their utmost capacity. They never inhale more than a third of what they should to burn up the bacilli that have made a lodgment in that part of the lungs which have been deprived of fresh air. They shut themselves in close, ill ventilated rooms in the fall, and do not permit themselves to get a breath of fresh air until spring. One bacillus in such a lung will produce more than sixteen million in twenty-four hours. They often spit upon a handkerchief, and each sputa contains three million germs and in twenty-four hours over six billions. If any of this sputa dries, the germs float and we inhale them, we breathe them in, and if they find the right soil, you can see how fast they propagate. You hear a great deal about consumption being contagious. The germs are floating everywhere, even in this room, but don't be alarmed. Physicians, nurses, members of the family in attendance, washerwomen and ragpickers never take it if they get a fair amount of fresh air. If you could only see the air of this room under a microscope, you would want to get out. As fresh air is a germicide, no one ever need take consumption, as fresh air costs nothing. I always expel all the air from my lungs when I leave a crowded room, and fill them with fresh air as soon as I get outside.

Be sure to have your sleeping room windows open more or less, as the weather may be, and you will be less subject to take on any disease, which is usually brought on by overeating, eating at improper times or improper food and staying in ill-ventilated rooms.

* By L. W. Curtis, M.D., in Health Culture.

The results obtained by the Nobel Dynamite Corporation in 1896, while not quite as good as expected, have been sufficient to warrant the payment of a dividend of 12 per cent. for the year, says the Engineering and Mining Journal. The capital is $9,127,000, in $50 shares. The net profits in 1896 amounted to $1,101,599, and the sum paid as dividend was $1,089,450. The report says that the business was good during the year, except in Germany. It is proposed now to establish factories in the United States.

ENGINEERING NOTES.

In April last there were recorded 105 train accidents in the United States, of which 36 were collisions, 63 derailments, and 6 other accidents. Nine accidents were due to road defects, 32 to defects in equipment, 15 to negligence, 4 to unforeseen obstruction, while 43 are "unexplained."

The production of coal in France in the second half of last year amounted to 14,736,819 tons, as compared with 14,311,596 tons in the corresponding period of 1895, showing an increase of 415,233 tons. Of the coal raised in France in the second half of last year, 8,791,888 tons, or about 60 per cent., were produced in the basin of the Nord.

There has been forged at Darlington, and is to be sent to Belfast, a stern frame weighing 41 tons; while after brackets are still heavier—55 tons gross. These castings are records in weight, for the Oceanic, now building in Belfast. It is, however, a curious feature in the story of the building of this modern leviathan that most of the material will be rolled, cast, and forged in England for this Irish built steamship.

In the course of the experiments on materials which the United States government have instituted, stone was not overlooked. According to the American Architect, it has been found that the temperature and moisture have a very great influence in determining the resistance of stone. In order to measure the permanent expansion which is known to take place in stones after soaking in water, a large number of samples were soaked in water at 32 Fah., then in water at the boiling point, and again in cold water, and afterward dried. On measurement, all the stones so treated were found to be larger than before, the actual linear expansion being from one-fifth to one-tenth of one per cent. On testing for resistance to various strains, however, the strength was found to be greatly affected by the water treatment.

The London Times says: "The congress of the German and Austro-Hungarian Association for the Promotion of Inland Navigation has just been held in Vienna. A protest was raised against the agrarian opposition to the development of inland navigation. It was pointed out that the agricultural classes greatly underestimated the value of such facilities for disposing of their products. Among other projects reported on were the Danube and Oder, and the Danube, Moldau and Elbe canals, and the proposed connection of the river Isar at Munich with the Danube. The question of utilizing the water power in the Moldau-Danube canal to generate electricity was also considered. The Biwa-Kioto canal, in Japan, was referred to as providing power not only for traction on the canal itself, but for lighting towns along its banks and for driving the machinery in a number of factories."

There was recently launched from the Elswick shipyard of Sir W. Armstrong, Whitworth & Company (Limited), Newcastle, the first-class cruiser O'Higgins, which is being built to the order of the Chilean government. The principal dimensions of the O'Higgins are as follows: Length, 412 ft.; breadth, 62 ft. 9 in.; draught (mean), 22 ft.; displacement, in tons, 8,500. Her armament will consist of four 8 in. Elswick quick firing guns; ten 6 in. Elswick quick firing guns; four 4.7 in. Elswick quick firing guns; ten 12 pounder Elswick quick firing guns; ten 6 pounder Elswick quick firing guns; four machine guns; three torpedo tubes. She has an armor belt extending over the greater portion of her length, 7 ft. wide, and 7 in. to 5 in. at the ends. The two barbettes, containing 8 in. guns, are of steel 6 in. in thickness. The casemates are 6 in. thick, and the conning tower 9 in. thick. The protective deck is 2 in. to 1½ in. in thickness. The total coal capacity is 1,200 tons, and the guaranteed speed is 21¾ knots. The O'Higgins is sheathed with wood and coppered.

The Purdue University has closed a contract with the Schenectady Locomotive Works for a new locomotive to be used in its engineering laboratory, in connection with courses in railroad engineering, says The Engineer. The new locomotive will possess a number of features which are quite new. It will carry a steam pressure of 250 lb. and will have cylinders so arranged that it may be used as a simple or a compound engine. The cylinders and saddle will be made up of different castings, and the centers will be so chosen as to allow the use of cylinders up to 30 in. in diameter. Several cylinders will be provided, and these, with a suitable series of bushings, will allow for different cylinder ratios in compound work. The whole machine will thus afford facilities for dealing with conditions quite beyond the limits of present practice. From its place in the laboratory, the old locomotive, hereafter to be known as "Schenectady No. 1," and which in the course of its six years' sojourn in the laboratory has been run an amount equivalent to 20,000 miles, and has served in an experimental study of many important problems connected with locomotive design, will pass into active service on the road, while the new engine, "Schenectady No. 2," will take its place upon the testing plant.

Since the introduction of torpedo boat destroyers considerable inconvenience has been experienced in consequence of the excessive vibration which is set up when these vessels are steaming at high speed. Various experiments have been carried out by the dockyard officials and naval engineers with a view to discover some means to overcome the difficulty, and in some cases the vibration has been somewhat reduced. Messrs. Laird Brothers, of Birkenhead, who have already completed six destroyers of various types and have four more in course of completion, have apparently solved the problem by a series of successful experiments in the Quail, a thirty knot destroyer, recently delivered at Devonport. This vessel underwent a trial with two balanced weights, weighing collectively 540 lb., fitted to her high pressure crank webs, while two more weights, weighing collectively 645 lb., were attached to her low pressure crank webs. The engines were run at various revolutions up to their full speed, and the corresponding vibration of the vessel was noted. It was found that the vibration, both horizontal and vertical, at a speed of 280 revolutions, was only one-half that which had been recorded before the balance weights had been fitted, while the engines ran steadily throughout.

MISCELLANEOUS NOTES.

The United States Department of Labor estimates the value of goods produced in the various penitentiaries of the States and Territories in 1895 at about $20,000,000.

The existence of a clear, crystal-like mineral, which, when looked through, produces two images of a single object, is one of the curiosities of science. It is stranger still that the only known supply of this double refracting spar is found in Iceland, and is controlled by the Danish government. The mine is located on the east coast of Iceland, about four miles from the trading station of Eskifjord, on the mountainous slope 350 ft. above the sea level. This mineral is used largely in optical instruments, polarization apparatus, and the like, and as the supply of the mined mineral has been exhausted, the mine having been closed for some years, the Danish government has recently leased the mine to its former owner. A pound of this mineral is worth about twenty seven dollars.

America is still maintaining its new reputation as an exporter of manufactures, says Industries and Iron. The returns for March of this year, recently issued, show that the valued total exceeded by no less than $2,000,000 the heaviest preceding totals for the same month, and exceeded by 30 per cent. the total for March, 1896, and by 60 per cent. the total for March, 1895. The whole of the figures relating to this relatively new traffic are too long to be enumerated here; but, taking them as a whole, their general aspect seems to show that the United States is in possession of what may very likely prove to be a staple, even if not a greatly increasing, trade in her manufactured products abroad. It is true that the promises of extensive exports of steel rails and billets have hardly been carried into effect, but in cycles and machine tools there is clearly a rapidly expanding commerce, with England particularly.

According to L'Echo des Mines, Paris, bullets of paper covered with aluminum are the latest thing in ammunition. "This invention, made by a French officer, tends to do away with the seriousness of wounds made by lead balls, or those with steel coverings, owing to the rupture of the bony parts. According to the patent granted to Richard Lüders, of Görlitz, the precision of fire is in nowise affected, but the passage made by the projectiles through the body is absolutely straight and permits of a rapid closing of the wound. As the number of the wounded will be as large as formerly, and as in most cases their incapacity will be as complete, we ought to look upon this discovery as calculated to satisfy the sentiments of humanity. But, nevertheless, the innovation has small chance of success, for we must recollect that, in war, unfortunately, the end sought is to put the largest number of men possible into a condition where they will be unable to bear arms for the longest time."

In the June Century there is an article by Prof. W. O. Atwater giving the results of experiments at Wesleyan University, during which men remained for several days in a small, copper lined room. The object of the experiments was to determine "How Food is Used in the Body," and Prof. Atwater says: The inference is that the people in professional and business life in the United States, where labor is mostly mental and indoors, are inclined to eat more than they need, and that the special excess is in the fuel ingredients, that is to say, the fats and carbohydrates. Taking the results of these and various other experiments together, the details of which cannot be quoted here, we are, I think, justified in believing that the diet of a very large number of people is out of balance. It contains an excess of food material, and this excess is largely due to the eating of fat meats, sugar, and the starchy foods. These results of accurate observation and experiment thus accord with and explain the current opinion of hygienists as to our ordinary habit of overeating.

On steamships one often hears the expression "slip of the wheel," says the Mining and Scientific Press. Now the meaning of this may be explained in a very simple manner. It is the difference between the actual distance run and the distance that would have been covered had the propeller acted upon a solid substance instead of a fluid. In other words, the expression may be understood as the lost motion of the propeller. It is usual to allow a certain number of revolutions to the propeller or paddles to the mile, and at the end of a stated time the estimated distance run by the ship, according to the number of turns made, is compared with the actual distance run by the ship according to observation of the heavenly bodies or by the patent log, and the difference between these two records is expressed as a percentum and entered in the log book as "slip of wheel." Retardation by reason of head winds and high seas comes under the head of slip. For example: If the distance run according to revolutions is 100 miles, and the actual distance run is 75 miles, the slip of wheel is 25 per cent.

It is an idiosyncrasy with Prof. Hughes, inventor of the microphone, that his remarkable inventions have all been worked out with the most simple and commonplace tools. Thus, in devising the microphone, the apparatus was of the most primitive character, and, with the exception of a Bell telephone receiver, could not be appraised at more than a few pence. This apparatus had a child's halfpenny wooden money box for a resonator, on which was fixed by means of sealing wax a short glass tube filled with a mixture of tin and zinc, the ends being stopped by two pieces of charcoal to which were attached wires, having a battery of three small Daniell cells—consisting of three small jam pots—in circuit. The wires were led away to a Bell telephone placed in an adjoining apartment. The money box, which had one end knocked out, served as a mouthpiece or transmitter, while a Bell telephone was used as a receiver. Sounds scarcely audible, and some absolutely inaudible, to the unassisted ear, were by means of this apparatus delivered with startling loudness through the Bell telephone. Numerous experiments of the utmost importance to physicists were carried out by Prof. Hughes with this apparatus, and with modifications of it, all proving that he had succeeded in producing the simplest and most powerful electric articulating telephone ever known.—Invention.

SELECTED FORMULÆ.

Aureol, a New and Harmless Hair Dye.—A writer in the Deutsche Med. Zeitung contributes the following formula for making a perfectly harmless hair dye which, from the golden tint produced, is called aureol. The dye consists of two liquids, used in equal parts. The first is a 3 per cent. solution of hydrogen peroxide. The second consists of—

Metol	10	parts.
Amidophenol hydrochlorate	3	"
Monamidophenylamin	6	"
Sodium sulphite	5	"
Alcohol	500	"

Dissolve the sodium sulphite in the alcohol, and add the rest of the chemicals. In use equal parts of the two liquids are taken, and only so much as is necessary at the time should be mixed. The hair is first freed from grease, etc., by washing with plenty of soap and thoroughly rinsing, and, after drying, the dye is applied with a comb with fine teeth.—National Druggist.

Test for Lubricating Oils.—The American Electrician gives the following simple tests for lubricating oils: A good test for oil is to place single drops of different oils in line upon a piece of plate glass about 2 feet to 2 feet 6 inches long, one end being raised about 6 inches to 8 inches to form an inclined plane. This test should be conducted in a room where there is little or no dust. The drops of oil start from the top of the inclined plane upon a race with each other. The first day sperm oil will be found in the rear, but after a time it will overtake the others, and be found in motion even after some others have dried up. An oil having a light body runs quickly and dries quickly, but an oil that has both a body and a free flow will readily be detected by this test. An oil may have a good body and yet tend to gum badly, which quality will also be easily detected upon the glass. A good test for the presence of acids is to put small quantities of oil in copper dishes, which are easily made by depressing bits of sheet copper with a round faced hammer. If acid is present, it will attack the copper and produce verdigris. As a result of experiments carefully made and extending over a year, it was found that iron was least affected by seal oil, and most by tallow oil when it is not deacidized. Brass is not affected by rape oil, least by seal oil, and most by olive oil. Mineral lubricating oil has no action on zinc and copper, acts least on brass and most on lead. Lard oil acts least on tin and most on copper. Sperm oil acts least on brass and most on zinc. From the tables given it is found that mineral lubricating oil has, on the whole, the least action on the metals experimented with, and sperm oil the most. For the journals of heavy machinery, either rape or sperm oil, in admixture with mineral oil, is the best to use, as they have the least effect on brass and iron, which two metals generally constitute the bearing surfaces of all engines.

Heat Indicating Paint.—"At a recent meeting of the London Physical Society," says Industries and Iron (Lit. Digest), "Dr. Thompson exhibited specimens of a heat indicating paint composed of a double iodide of copper and mercury, originally discovered twenty years ago by a German physicist. At ordinary temperatures the paint is red, but when heated to 95° C. (200° F.) it turns black. Paper painted with this composition and warmed at a stove exhibits the change in a few seconds. A yellow double iodide of silver and mercury is even more sensitive to heat, changing from yellow to dark red at a temperature of 45° C. (113° F.) Many suggestions have been made from time to time as to the utility of such a paint; for instance, it has been suggested that it might be used on machine bearings to give warning of their heating, but we opine that the costliness of the material would in a great degree prevent its adoption either for this or any other of the numerous purposes to which it might otherwise be well applied."

Ant Exterminator.—(1) Powdered borax sprinkled around the infested places will drive them away, as also will powdered cloves. Grease a plate with lard, they will leave sugar to go to it, and then turn them into the fire; cracked nuts will answer the same purpose. Oil of turpentine run into the cracks with a sewing machine oil can.

(2) A good preventive for the inroads of ants is a stripe of carbolated petrolatum about half an inch in width drawn about the places frequented.

(3) Cape aloes .... 1 pound.
Water .... 1 gallon.
Boil together and add to the mixture:
Camphor, in small pieces .... 6 ounces.

(4) Sprinkle their haunts with quicklime containing a twentieth of its weight of powdered camphor.—Pharmaceutical Era.

Photographic Hints and Formulas.—

From Liesegang's Photographischer Almanach.—(Amer. Photo. Jl.)

Varnish.—Ground glass substitute (Lauler):

Ether	100	c. cm.
Sandarac	10	grm.
Dammar	3	"
Dissolve and filter, then add		
Benzole	50–60	c. cm.

The more benzole, the coarser the grain.

Varnish (Valenta).—

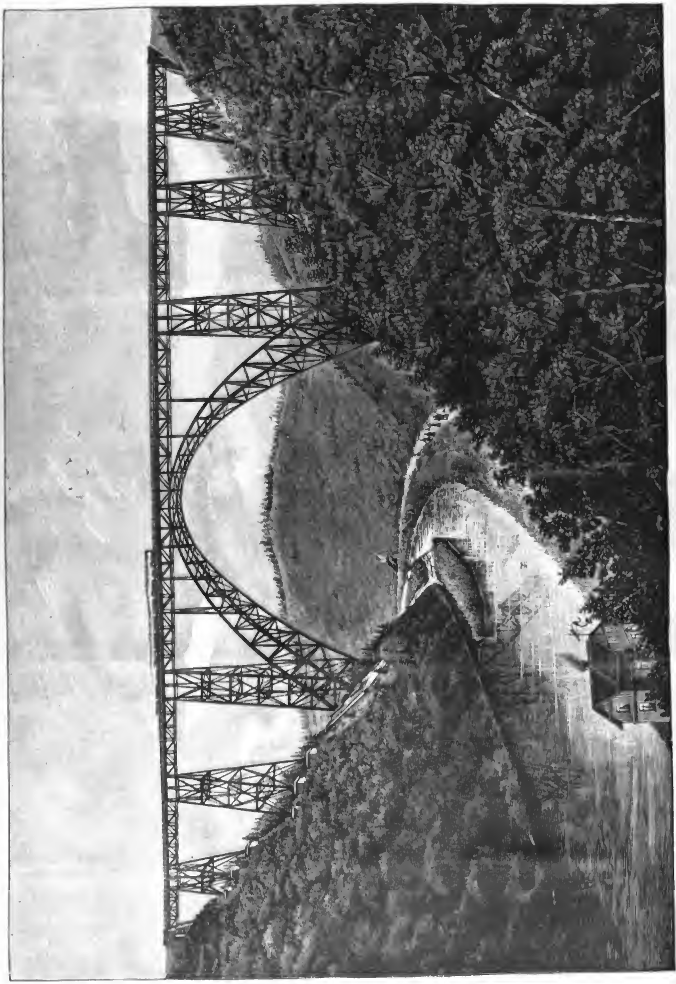
Benzole	400	c. cm.
Aceton (pyroacetic spirit)	400	"
Alcohol (absolute)	100	grm.
Sandarac	100	"

The solution is to be warmed in a water bath and filtered, the negative can then be coated without previous warming.

Retouching Varnish for Negatives.—

(a)	Alcohol	80	c. cm.
	Sandarac (pulverized)	15	grm.
	Turpentine	5	c. cm.
	Oil lavender	4	"
(b)	Alcohol	32	c. cm.
	Ether	2	grm.
	Camphor (crushed)	5	"
	Water	10	c. cm.

Both solutions are to be mixed several days before wanted, then decant and filter. The hardness of film increases with time.



THE RAILWAY BRIDGE OVER THE WUPPER VALLEY AT MUNGSTEN—305 FEET HIGH.

THE MUNGSTEN BRIDGE.

ON the day of the hundredth anniversary of Emperor I a peculiar fête was celebrated in the Rhine province. On that day the final touch was put to the bridge over the Wupper Valley at Müngsten.

The imposing structure was gay with numberless flags, and in the hours of the forenoon, accompanied by the joyful strains of a band, a procession of one hundred and twenty workmen approached. At their head were the directors and chief engineers of the Nuremberg company that had undertaken the building of the bridge and other great technical men. At the giddy height, in the middle of the vast parabola, a halt was made, and with the words, "To advance the common weal, to facilitate the traffic and in appreciation of the technical art!" the last three rivets were inserted. Then all joined with full vigor in the chorus of the well known hymn, "Nun danket alle Gott," and finally a good drink of beer from a mighty cask was enjoyed.

The total length of the bridge is 1,600 feet; the span of the arch is 524 feet; the breadth of the supports, 91 feet.

The pillars at the ends of the arch are 215 feet high; those on the banks, standing 98 feet and 147 feet apart respectively, are 151 feet and 79 feet high. The construction for the double tracks, which rests on the pillars, etc., is 19 feet high. The four abutments for the arch cover a total area of 3,767 square feet, and the sixteen stone bases of the four pillars on the banks 1,967 square feet.

In dimensions this bridge is, on the European Continent, surpassed only by the Garabit viaduct in southern France, which is built similarly, but rises 400 feet above the valley, and whose arch has a span of 541 feet.

The construction of the Müngsten bridge was begun from either side in the summer of 1893, and after all but the main span had been completed the free assembling of the span was commenced in 1896, in a manner never before attempted in practice.

The pillars on each side were connected by means of steel cables 3½ inches in diameter and were fixed by anchorage on the rock by means of hydraulic power.

Rotary cranes placed on the extremity brought ready mounted parts of 8 to 12 tons weight to their place of destination, where they were held suspended by ropes and mounted from travelling scaffolds. In this way the work progressed along the pieces added, and expensive scaffolding was avoided.

Unfortunately, some accidents are to be recorded as having taken place during the building, as, in spite of all precautions, three workmen found their death through falls from the structure. The opening of the new railway line Solingen Remsheid was intended to take place on July the first, and so a direct connection between the grand duchy of Berg and the lower Rhine is made.—Illustrirte Zeitung.

PUNCHING AND SHEARING MACHINES.

WE represent herewith a combined punching and shearing machine, and a simple shearing tool for profiled iron and steel, both manufactured by Mr. John Cameron, of Salford. The first of these interests more particularly ship builders, boiler makers and manufacturers of metallic framework. At its right it carries shears, at its left a punch, and in front a double punch for forming in the iron plates or the irons that constitute the carlings resting upon a vessel's floor timbers, or, if need be, in the latter themselves, the conduits arranged at the bottom of the hold to facilitate the circulation of water and allow it to flow toward the bilge pumps.

One of the punches is 3 inches in diameter and is capable of piercing carlings three-fourths of an inch in thickness. The other, whose rectangular section measures 2·25 inches by ¾ of an inch, serves for forming delivery channels in plates 0·9 of an inch thick. The hollow or overhang of the two branches of the frame is equal in both cases to 21 inches.

The two punches are capable of being actuated separately. They are used in rotation, and this dispenses with changing the punches and prevents the loss of time caused by this operation in machines provided with a single punch.

The punches are mounted in a strong cast steel carrier bolted to a cast iron slide actuated by the eccentric of a steel shaft. The rear part of the frame of this double punch is carefully trued, dovetailed together and bolted to the front of the principal machine. The punch placed at the left of the latter is capable of forming holes 1½ inch in diameter in iron plates of the same thickness. Its soft steel slide is provided with a starting mechanism and is actuated by a cam device that gives the punch a quick elevation followed by a pause. The hollow of the frame measures 34 inches.

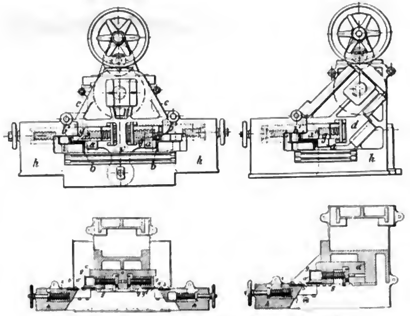
As to the shears placed to the right of the machine, those are capable of cutting plates 1⅛ inch in thickness at a distance of 34 inches from the edge, since the hollow of the frame is identical with the preceding.

The flywheels of these tools are of cast iron. At the place where the cams act, they carry tempered steel plates, and, at the front, coupling rods that serve to elevate the punches.

To the third face of the whole, that is to say, to the back, is bolted the steam motor that actuates the three tools. The whole weighs twenty-nine and a half tons.

The use of special machines for shearing or rapidly and cleanly cutting profiled iron and steel, at right angles or according to any degree of obliquity, is as indispensable in shipyards as at points where large iron frameworks or bridges are under construction.

DOUBLE TYPE. SIMPLE TYPE.



HORIZONTAL SECTIONS ACCORDING TO THE AXIS BLADE CARRIER SLIDES.

FIG. 2.—SHEARING MACHINE FOR Z IRONS.

The methods employed must not only assure a clean and accurate cut, but also prevent any distortion at the extremities of the pieces acted upon. They must also permit of passing, without complication or loss of time in regulations, from one dimension to another for the same profile and from an angle iron to an I iron, or from the latter to a U or a Z iron, according to the needs of the moment.

Mr. Cameron has devised several types of machines to this effect, all of which are identical in principle and consist essentially in the use of a flat blade cutting by its edges and presenting either a central piece or two lateral pieces that first enter the metal and prepare the way for the oblique cutting edges, which penetrate the metal progressively up to a complete shearing.

This blade operates between three pairs of counterblades fixed permanently in the base of the machine, which, at this place, presents a wide rectangular cavity. Two of these pairs are vertical and at right angles with the third, which is consequently horizontal. They thus extend along three sides of the cavity in the base. Moreover, one counterblade of these pairs is in front of, and the one that corresponds to it behind, the movable blade, and between them there is sufficient space to allow the latter to pass. The blade, in its descent into this sort of matrix, acts after the manner of a cutting punch upon the beam to be sheared, and removes therefrom a band of metal of the same width as the latter.

It is possible also to cut Z irons with these machines, but in this case the wings, during the operation, necessarily undergo stresses that tend to distort them.

This tendency, moreover, is so manifest that, for profiles of this kind, Mr. Cameron has devised a special shearing machine.

The two models of machines, a double and a simple one, that have been devised for this purpose are shown in Fig. 2. They are characterized by the use of two movable blades, a and a', that operate conjointly with two fixed counterblades, b and b'. In the double shears, a set of blades is arranged on each side of a piece, c, which is jointed at its lower part to the base, h, and is moved upward by the eccentric of a central shaft that receives its motion from spur gears actuated by a belt or by a special motor. The driving mechanism is identical in the simple shears, but its eccentric shaft actuates a frame, d, that slides in the base and carries a simple set of blades.

One of the movable blades, a, is fixed directly to the piece, c, or to the frame, d, while the other, a', is carried by the slide, g, which is regulatable by means of a screw and nut. A similar arrangement is given to the counterblades, b and b'. The first is stationary, while the second is mounted upon a slide, l, which may be displaced by a screw carrying a maneuvering hand wheel. The operator is thus able to regulate the position of the blades, a' and b', according to the height of the web of the Z iron. The cavities formed in the base for the passage of the iron to be cut, as well as the form of the slides, l and g, permit of giving the oblique position that corresponds to the angle of cutting.—Revue Industrielle.

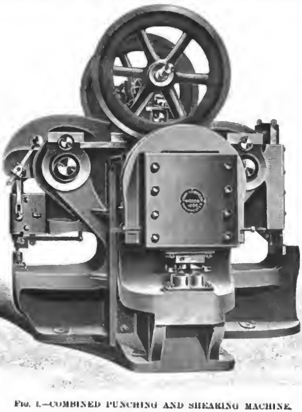


FIG. 1.—COMBINED PUNCHING AND SHEARING MACHINE.

ON his new Arctic expedition Lieut. Peary intends to take with him not only Esquimau men, but also women. The Esquimau is a pronounced family man, and prefers his wife to the North Pole.

BRITISH VERSUS AMERICAN MANUFACTURED PRODUCTIONS.

We are accustomed to hear it said that the American people are a people of great inventive genius; that they are more adaptive, and possessed of greater mechanical skill than our own people; and that they are destined in course of time to become the mechanical engineers and manufacturers of the world. No doubt the American machine tool makers and locomotive builders have made progress during recent years. But they have now had a considerable time to get their hands in, and should be able, if ever they are to make headway against European countries, to make it now. They have cheap raw materials, fairly cheap labor, home protection, and other elements in their favor, and yet they only export machinery and motors of all kinds to the value of about two and a half millions sterling a year, as compared with an average of about six times that value exported from the United Kingdom under the same heads. Nevertheless, the United States are undoubtedly "on the make," and very much in earnest. The American people have made up their minds to take possession of every market open to them, and hence it is not likely to be an unprofitable study if we seek to find out what they are doing, or have already done, that may affect our own mechanical industries.

The most important item in the list of American manufactured exports for a number of years past has been locomotive engines. The locomotive industry has assumed such large proportions in the United States that the home requirements, vast as they are, are totally insufficient to keep it employed. The number of locomotives exported from the United States has increased from year to year, until it is now between five and six times what it was six years ago. In other words, during that period the number of locomotives exported has increased from about fifty per annum to over three hundred. American locomotives are now annually exported to Russia, China, Japan, South and Central America, Canada, our Australasian Colonies, Cuba and other countries.

The amount of labor expended upon a locomotive engine is considerable, probably 75 per cent. of its total cost. Labor, however, is not a cheap commodity in the United States—certainly not cheaper, in nominal value, than in our own country. And yet the cost of building locomotive engines must be less in America than in Great Britain, or we should not witness a larger demand for American locomotives than for those built at home. The difference of cost must, moreover, be mainly a question of labor, for none of the materials of construction, on an average of the last ten years, have been cheaper on the other side of the Atlantic than on this side. Nor, when we speak of labor, do we necessarily mean that the American is a better or more hardworking artisan than the Englishman or Scotchman. It is not so much a matter of hard or intense labor as it is a matter of type. American locomotive builders, as a rule, adopt certain types, and stick to them. English builders, on the contrary, build a hundred different types to meet the fads of as many different locomotive engineers, many of them having the long purses of plethoric railways to draw upon, and caring little for economy so long as they can get their ideas tested to demonstrate the possibilities of special results.

Another point that greatly favors the American locomotive builder—and, indeed, the American manufacturer generally—is the fact that he not only sticks to particular types, which renders duplication easy and inexpensive, but he has a much larger and more steady market to rely on, and is, as a rule, more steadily employed than the British locomotive builder. This counts for much in reducing the heavy item of standing charges. The difference between one establishment working full time and another establishment working only half or three-quarters time is all the difference between making a profit and incurring a loss at a given schedule of prices. A further manifest advantage is gained by the American system of manufacturing on a large scale. Some of the American locomotive works—such, for example, as the Baldwin and the Schenectady—are, in point of size, far ahead of any similar works in this country, although we are prone to boast of such works as Neilson's, Dubs', Beyer & Peacock's, and the Kitson Works, at Leeds. We all know that if a factory is producing a thousand copies of the same thing it can do so much more economically than if it produced only fifty or a hundred, and herein, again, the works of the United States possess a notable advantage, alike in buying and in selling. Finally, in reference to locomotive engines, it has been claimed again and again that the American types are simpler, more powerful relatively to cost, and otherwise better than our own. We do not admit the truth of such claims, of course. Locomotive engineers of the first rank are continually debating this point, and it is still unsettled. But there must be those in all foreign countries that buy American locomotives who are disposed to prefer American types, or we should not see those types make the headway which they have done. The Baldwin Works alone have produced from first to last upward of sixteen thousand locomotives, and are represented in most of the civilized countries of the world. No locomotive works in Great Britain have, as yet, come anywhere near this record.

The observations which we have applied to the special conditions of American locomotive works apply, mutatis mutandis, to the manufacture of machine tools, of which the Americans now export four times the volume and value that they did ten years ago. During the last two years this branch of American export business has greatly advanced. This increase is largely attributed to the growth of the cycle industry in Europe, the American machine tools being imported for that class of work especially, although they are making headway in other directions. In one case fifty automatic screw machines by the Cleveland Machine Screw Company were ordered in one lot and to go into a single plant, and whereas in former years the trade consisted mostly of orders for single machines, or at most a very few machines in any one shop, it now often takes the form of complete equipments for the production of a certain machine or article. During the past year business is said to have been so good with them that they have been under no necessity of soliciting orders, but people have for the most part pressed to know how soon certain machines could be delivered. The growth of this business is the more annoying because, as a recent writer has pointed out, there is nothing in these tools which our native mechanics could not have produced if they had only thought of it. It is hard to account for this higher perfection of light machine tool making on the other side of the Atlantic. We are apt to consider that in a new country things are inclined to be haphazard and makeshift, but we must not forget that the engineering history of New England extends almost as far back as that of Old England. The earlier British engineers perfected the standard machine tools, and the engineering industry of the country has been so great that makers have not been forced into what are known as "special lines." When the heads of firms find they can make a good income by selling the same thing over and over again, they do not seek fresh combinations—unless, indeed, they have a natural love for designing. It may be that it is here that the New Englander has now the most considerable advantage. In the past many of our own machine tool makers were men who were brought up in the shops—mechanics, made into business men and heads of firms by the force of circumstances, but still mechanics. They had mastered their craft in the school of necessity, and loved it for its association with early days, and as a means by which they reached prosperity. They sent their sons to expensive schools, where the spirit of mechanical ingenuity has been an unknown thing, classics and the politer branches of learning being considered all important. The result is found in our failure to keep pace with those who have been trained in a sterner school.

One of the largest importers of American machine tools is Mr. Charles Churchill, who says he has encountered very little disposition or inclination in England to copy American machine designs. This may be due not only to the Englishman's inclination to have and to embody his own ideas in machine construction, but also to the fact that the prices at which American machine tools are sold in Great Britain discourage attempts to compete with the same machines, since it is readily seen that in order to produce similar machines at the same price a similar plant must usually be put down for manufacturing them, and with little hope of producing them at the same or lower cost.

For more than thirty years Mr. Churchill has been selling in England all sorts of drill and lathe chucks of American manufacture, yet, so far as he knows, there is not a single American chuck maker in England. American steel balls are also making headway, and orders for over twenty million American balls were placed there in 1896. It is believed that over two hundred Cleveland Machine Screw Company's automatic screw machines were installed in Great Britain last year. Another American product that seems to meet with a very favorable reception is the gas furnace of the American Gas Furnace Company, of which Mr. Churchill is agent.

Within the last few years the British have lost a large part of the industry of manufacturing steel tubing, of which we formerly exported large quantities to the United States. Colonel D. L. Cockley, vice-president and general manager of the Shelby Steel Tube Company, may be said to have founded this industry in the United States. In a chance conversation he learned that bicycle manufacturers were using an immense amount of steel tubing, all of which was imported. The two companies at this time in operation in England were the Weldless and Credenda. Two representatives of the Shelby Company were detailed on a special mission. It required persistent ingenuity to gain entrance to one of these steelworks. Disguised as a workman one of the representatives finally accomplished the task. Eventually, Hudson & Gay, tube drawers, allowed them to make sketches of their works and operations. The English preceptor of the tube industry declared that sizes less than three-eighths of an inch and larger than one and three-fourths inches could not be made; but at the works of the Shelby Tube Company, now the largest in the world, it is turned out in sizes ranging from one-eighth of an inch to as large as three inches in diameter, in gage from 1 to 30, English standard. The metal used is steel billets or blooms, imported from Sandviken, Sweden. Large annealing ovens, fed by gas, soften the tubes after each drawing, the final pulling giving the material the proper temper. Numberless slowly revolving hydraulic-like cogwheels, with endless chains of immense power, do the stretching of the steel tubes when cold.

So far as the miscellaneous exports of iron and steel products are concerned, the statistics of the ten years ending 1895 show a remarkable advance as set out in the table that follows:

EXPORT OF LEADING DESCRIPTIONS OF AMERICAN MANUFACTURES IN IRON AND STEEL, 1886 TO 1896.

Year	Steel plates and sheets, 1=1,000 lb.	Steel rails, 1=1,000 tons	Wire, 1=1,000 lb.	Bar iron, 1=1,000 lb.	Steel ingots, etc., 1=1,000 lb.
1886.	0	4	8,036	1,519	272
1887.	564	2	9,612	2,131	134
1888.	619	5	12,734	1,508	207

Besides the above the United States export quantities of pig iron, band, hoop, and scroll iron, castings, car wheels, nails and spikes, saws and tools, stationary engines and boilers, and stoves and ranges. The enumerated exports of iron and steel have increased from a value of over two and a quarter million dollars in 1885 to nearly seven and three-quarter million dollars in 1895. During 1896 still more notable progress has been made, and we are almost afraid to face the figures for the year 1897, which, as those published in the Review have already shown, has been making industrial history for the United States at a very rapid rate.—The Iron and Coal Trades Review.

BABBITT METALS.

By C. Vickers.

"Genuine" babbitt is composed of a small quantity of copper, added to tin and antimony. No lead is used, for the adjective "genuine" is applied especially to distinguish it from the cheaper grades containing lead.

There is considerable temptation to adulterate it with lead, owing to the difference in value of lead and tin; one pound of lead added to 100 of "genuine" makes a gain of about 18 cents. The character of the alloy would not be greatly altered, but when the purchaser pays for the best he certainly has a right to expect it. Fortunately, it is easy to detect such adulteration; take a piece and use it for a pencil; if it makes a mark, then it contains lead, as a small amount of lead added to tin causes the latter to mark paper. The following proportions may be used in making this alloy:

No. 1.	Copper	4 lb.
	Tin	8 "
	Antimony	8 "

This forms the hardening, as it is called. First melt the copper, add the tin and afterward the antimony; remove from the fire and let cool down to a dull red heat, then add 16 pounds more tin to increase the fusibility of the hardening. This makes 32 pounds hardening, add this to 64 pounds more tin—the proportions of tin to hardening thus being two to one. The additional tin should be melted separately in a kettle or suitable vessel, and the hardening added either in ingot form or direct from the furnace; in the latter case be sure the tin is all melted, otherwise an accident might occur by the hot metal from the furnace falling on the damp end of a projecting ingot.

To prevent loss by oxidation, the contents of the kettle should not be heated much above the melting point. In cases where a cheaper composition is desirable, the following can be recommended:

No. 2.	Genuine hardening	32 lb.
	Tin	64 "
	Lead	98 "

This forms a good alloy; another one is:

No. 3.	Hardening	16 lb.
	Tin	50 "
	Antimony	20 "
	Lead	80 "

In mixing this alloy, first melt a portion of the lead, say 40 pounds, in the kettle or in a crucible in the furnace, bring to a dull red heat, add the antimony, in small pieces, when melted add the balance of lead. Do not attempt to melt the antimony without the lead bath, as it is a volatile metal and there would be loss from oxidation.

In making all alloys containing hardening, a furnace is necessary, on account of the heat required to melt the copper. The following mixtures contain no copper, and are fairly good compositions:

No. 4. For hardening, take	Lead	145 lb.
	Tin	40 "
	Antimony	20 "

Melt 145 pounds lead and 40 pounds tin and add 52 pounds hardening.

No. 5. For hardening.	Lead	48 lb.
	Antimony	26 "

Add this amount to 132 pounds lead. The hardening is used in this merely to form a bath for the antimony, and any portion of the 200 pounds lead may be taken. This is cheap and soft.

Another cheap composition is formed as follows, and is known as "hard lead;"

No. 6.	Lead	80 lb.
	Antimony	20 "

Hard lead is a better metal than No. 5. It is largely used for lining car journal bearings. It may be improved by the addition of tin as in the following:

Hard lead	100 lb.
Tin	100 "

This is given as an illustration. A great variety of alloys can be made by taking hard lead as a base and adding tin in varying quantities.

Zinc is sometimes added to cheap alloys. It has a tendency to form unsightly ingots, owing to the formation of bubbles on the surface. It should be kept out of strictly high class babbitt. It has been suggested that the addition of aluminum improves babbitt metals. But, while this may be true, the writer does not consider that the improvement will be sufficient to pay for the increase in cost. Bismuth is also sometimes used, but it possesses no advantage over antimony and is more expensive.

Before pouring into ingots, the dross which forms a scum on the surface of the liquid metal should be skimmed off and saved. The percentage of dross may be lessened by the use of a flux. Resin, tallow, or grease of any kind is a good flux for babbitt alloy. When any considerable amount of dross has accumulated, it may be melted by adding resin and small quantities of crude sal ammoniac. The flux must be thoroughly mixed into the pasty mass, until it liquefies, and the dross floats on the surface in the form of a greenish dust. It may then be skimmed off and the metal poured into ingots.—Machinery.

The damming of the Rio Grande River by an English corporation for irrigation purposes is objected to by the Mexican government, in a communication to the State Department of the United States, as seriously interfering with navigation, says the Engineering News. The proposed dam was to be located on the American side, at Elephant Butte, New Mexico, and authority for its construction was granted by the Secretary of the Interior, under the Desert Land Laws. Attorney General McKenna has now decided that the construction of the dam would injure persons along the Mexican side of the river, and would therefore be a violation of international law. He has, consequently, instituted civil and criminal proceedings to stop the work. The projected international dam at El Paso would also become useless if the Elephant Butte dam were erected, according to a report made to the War Department by Col. Anson Mills, U.S.A., and international boundary commissioner.

THE INTERNATIONAL GEOLOGICAL CONGRESS IN RUSSIA.

THE International Geological Congress may be said to come of age this year, for it was founded at Philadelphia in 1876, at a meeting held under the presidency of the veteran James Hall. The first organized session was held at Paris in 1878, and since then meetings have taken place at Bologna, Berlin, London, Washington, and Zürich. The seventh session is to be held at St. Petersburg, with Prof. A. Karpinsky as president.

The ordinary meetings of the congress will be held in the rooms of the Imperial Academy of Sciences at St. Petersburg. There will be a preliminary assembly of the members on August 28, the formal opening will take place on the following day, and the meeting will terminate on September 4. According to the Russian calendar, these dates will be twelve days earlier, namely, August 16, 17, and 23.

The meetings will extend over eight hours. From 9 till 10 a. m. the committees of the congress will deliberate; from 10 till 2 p. m. there will be discussions on questions proposed in the programme of the organizing committee. One hour is then set aside for visits to museums and to the exhibition of maps, sections, books, specimens and instruments—possibly some members may then take the opportunity of obtaining lunch. From 3 to 5 o'clock papers of a general character will be read, and these will be so arranged that only one branch of geological science will be discussed each day.

The organizing committee will reopen the subject of the unification of geological nomenclature. The larger divisions of the earth's history must be based on general paleontological characters, and in defining the several systems attention will be specially given to the study of pelagic life and the evidences of organic evolution. In order that a system be well established it must be capable of subdivision into stages characterized by well marked pelagic faunas, and these should have a European or equivalent value. It is recognized that substages have only a regional value, while minor divisions have but a local character, and with these the congress does not deal. The divisions, in short, which the assembly will be called upon to discuss are those of geological time, based on the occurrence of successive groups and zones of fossils; the purely stratigraphical divisions are essentially regional or local, and they may reasonably be left for each country to fix according to its own necessities; for they are all important in the interpretation of the structure of a district, in determining its economic resources, and in explaining the origin of its scenery. On the other hand, when we seek to trace out the history of the great changes which the earth at large has undergone, the more comprehensive life divisions are all important; and these only can be universally applied, and, we hope, universally adopted. It is true that life divisions are no more to be rigidly defined than are stratigraphical divisions in the rocks, but fossils are the only guides for correlating the formations in countries far apart. There should be no serious disagreement among geologists, at any rate with regard to the principles of correlation; and there is no reason why, after full and friendly discussion, a particular nomenclature should not be generally accepted. It need not interfere with our local divisions, any more than great chronological terms, if applied to human history in general, would interfere with our own time divisions marked by the reigns of successive monarchs.

The organizing committee will also deal with the subject of petrographic nomenclature, in the hope of reducing the number of terms now used, and of preventing unnecessary names being introduced. In petrology, as in paleontology, one is nowadays in constant need of a dictionary or glossary, or table of synonyms, to understand the various names of rocks or rock structures and fossils.

The scheme for excursions in connection with the congress is an elaborate one. There will be excursions both before and after the ordinary meeting, and those who have time and money will have grand opportunities of visiting many parts of the Russian empire in Europe.

Prior to the congress there will be three excursions; namely, to the Ural regions, to Esthonia, and to Finland. The Ural excursion is timed to take place between July 28 and August 27. There will be a general gathering of the party at Moscow on July 29, and those who join are advised to take thick boots, warm clothing, and waterproof cloaks, for there will be rough walking as well as long journeys in open carriages and on horseback. Messrs. Nikitin, Tschernyschew, Arzruni, Karpinsky, and Stuckenberg will act as leaders. The party will take train to Riazan, and thence journeying to Syzran, on the Volga, they will cross Jurassic, Cretaceous, and Tertiary strata. Thence from Samara to Oufa, Permian and Triassic rocks will be traversed, while onward to the Ural Mountains the party will pass over Carboniferous, Devonian, and Siluro-Cambrian strata, which present evidences of considerable metamorphism, and which, together with various schists, are penetrated by numerous eruptive rocks. The region is famed for its metalliferous deposits, and various mines in rocks bearing gold, copper, and manganese will be visited, as also will be the imperial stone-cutting works at Ekatherinebourg. The return journey will be made by Perm, Kazan, and Nijni-Novgorod.

The excursion into Esthonia, August 13 to 27, under the direction of M. Schmidt, will be by rail to Reval, on the Gulf of Finland, and then a visit will be paid to the Isle of Dago, when attention will be given to the fossiliferous Upper and Lower Silurian rocks.

The excursion to Finland will be made under the guidance of M. W. Ramsay. The members will assemble at Helsingfors on August 21, and return to St. Petersburg on August 28. Tammerfors and Lavia will be reached, and attention will be directed to the glacial phenomena and the various crystalline rocks.

After the meeting of the congress is over, the principal excursion will be to the Caucasus, leaving St. Petersburg on September 5, and arriving at Moscow on the following day. The excursion party will then be divided into three sections, A, B, and C. Section A will be conducted by Messrs. Nikitin, Tiouraw, Tschernyschew, Loutougin, Rongnéwitsch, and Konchin. Leaving Moscow, and traveling by Podolsk, the route will be over Jurassic, Carboniferous and Devonian rocks, and on the Cretaceous strata of Koursk and Kharkow. Thence the party will proceed to Rostow, at the head of the Sea of Azov, examining a mercury mine and certain mineral springs, and ultimately reaching Wladikavkaz, on the northern side of the Caucasus Mountains. Section B will start, under the guidance of Messrs. Pavlow and Amalitzky, from Moscow to Nijni Novgorod, across Jurassic and Triassic formations to the Cretaceous rocks of Simbirsk on the Volga. Journeying southward, they will visit asphalt quarries, and by means of steamer and railway they will proceed along the plains of the Volga and the borders of the Kirghis Steppes to Astrakhan and Wladikavkaz. Section C will be under the direction of M. Sokolow, and will journey to Kiew, on the Dnieper, paying especial attention to the Tertiary and Post Tertiary deposits. Following the river to Alexandrovsk, the party will ultimately join the two other sections at Wladikavkaz by way of Rostow.

Thus united, the whole party will proceed across the mountainous country to Tiflis, under the direction of M. Loewinson-Lessing, some few members separating for a while to examine a glacier under the guidance of M. Kolenko. Tertiary, Cretaceous, Jurassic, and metamorphic rocks will be seen. From Tiflis all will proceed to Baku, on the borders of the Caspian, and thence separating into two portions, they will traverse the mountainous region from east to west, and unite again at Rion. Some may spend a week in the Caucasus, examining the Maunisson glacier; others will have an opportunity of visiting Mount Ararat.

Those who desire to still further continue their field studies among Cretaceous and Jurassic rocks may take part in a general excursion into the Crimea. They will proceed by steamer from Batoum to Kertch, and eventually, on October 5, there will be a reunion of all the remaining excursionists at Sébastopol. Thus will terminate the great programme of expeditions planned by the geologists of Russia.—H. B. W., in Nature.

THE BAKERIAN LECTURE—ON THE MECHANICAL EQUIVALENT OF HEAT.*

THE purpose of this research differs essentially from that of any previous research on the mechanical equivalent of heat. In order to diminish the loss of heat by radiation, as well as to obtain the equivalent for water in the neighborhood of ordinary temperatures, the ranges of temperature over which the previous dynamical measurements have been made are greatly less than the standard interval between the physically fixed points of temperature to which all thermal measures are referred, and so have of necessity involved the use of scales, the intervals of which depend on the constancy of the relative expansions of such substances as glass, mercury, and air. On the other hand, in this research the object has been to determine the mechanical equivalent of the total heat necessary to raise the temperature of water over the standard interval of temperature, and thus to obtain directly the equivalent of the mean specific heat between the freezing and boiling points.

This undertaking is the result of the occurrence of circumstances which afforded an opportunity such as might not again occur. This consisted in the facilities offered by the appliances which formed the original equipment of the Whitworth Engineering Laboratory, in 1888, the more essential of these being an engine of 100 H. P., working one of Prof. Reynolds' hydraulic brakes. This brake maintains any constant moment of resistance on the engine shaft, independent of the speed, all the work done being converted into heat, which appears in the rise of temperature of a steady stream of water flowing through the brake, the magnitude of which stream is independent of the load on the brake or the speed of the engine, and is under independent control.

The existence of the Manchester town's water, of a purity expressed by 3 grains of salts to the gallon, conveniently distributed in the laboratory, as well as auxiliary power, both steam and water.

Although unconsciously, the research was really commenced in 1889, when, without any intention of making a determination of the heat equivalent of the work done on the brake, but solely for the purpose of verifying the mechanical balance of the brake, provision for thermal measurements was added, and a system of trial instituted, in which the object sought was only that of obtaining consistent results over definite portions of the scales of uncorrected thermometers, eliminating the errors resulting from radiation by taking the differences of two trials. In these trials the temperature ranged from 40° to 50° F., and their development was continued over two years. Then it occurred to Prof. Reynolds that by the same method the great facility which this brake was then seen to afford would be available for the independent determination of the mechanical equivalent, if it could be arranged that water should enter the brake at the temperature of melting ice and leave it at that of water boiling under the standard pressure. Since then all that would be required of the thermometers would be the identification of these temperatures, and with a range of 180° the error in scale over one or two degrees would be comparatively of small importance. At first the difficulties seemed formidable; but on trying by gradually diminishing the supply of water to the brake when it was absorbing 60 H. P., and finding that it ran steadily under control of its automatic gear till the temperature was within three or four degrees of boiling, he further considered the matter, and during the next two years convinced himself of the practicability of the necessary additional appliances by preliminary designs. These consisted of:

(1) An artificial atmosphere or means of maintaining a steady air pressure of ½ atmosphere in the air passages of the brake.

(2) A circulating pump and water cooler, by which the entering water, some thirty pounds a minute, could be forced through the cooler into the brake at a temperature of 32°, having been cooled by ice from the temperature of the town's main.

(3) A condenser by which the water leaving the brake at 212° might be cooled down to atmospheric temperature before being discharged into the atmosphere and weighed.

(4) Such alteration in the manner of supporting the brake on the shaft as would prevent excess of leakage from the bushes in consequence of the greater pressure of air in the brake, since not only would the leaks be increased, but, when the rise of temperature was increased to 180°, the quantity for any power would be diminished to one-sixth of that for a rise of 30°, so that any leakage would become six times the relative importance.

(5) Some means by which assurance of the elimination of the radiation and conduction could be obtained, as with a temperature of 140° F. above the laboratory these would probably amount to 2 or 3 per cent. of the total heat.

(6) Scales for greater facility and accuracy in weighing the water with a switch actuated by the counter.

(7) A pressure gage or barometer by which the standard for the boiling points might be readily determined at 3° or 4° F. above and below the boiling point, so as to admit of ready and frequent correction of the thermometers used for identifying the temperature of the effluent water.

(8) Some means of determining the terminal differences of temperature and quantities of water in the brake, which would be relatively six times as large as with 30° rise.

These preliminary designs apparently demonstrated the practicability of the appliances, and also the possibility of their inclusion in the already much occupied space adjacent to the brake. But there remains still much to be done in the way of experimental investigation in order to obtain the data for proportioning the appliances.

In July, 1891, Mr. Moorby having undertaken to devote himself to the research, the experiments necessary for the appliances were at once commenced, and these, together with the construction of the appliances and then standardizing, and preliminary experiments while this was in progress, occupied till February, 1896, when Mr. Moorby commenced the main experiments, which were continued into July, 1896.

In these experiments the time of running was 62 minutes, the speed 300 revolutions a minute, on the speed gages. Observations of speeds, of the temperature of the inflowing and effluent water, and of the temperature of the air were made every two minutes. Observations of the slope of the temperature of the shaft were made every eight minutes.

The temperature of the inflowing water varied from 32·5° to 34°, and that of the effluent from 210° to 214° F. The effluent water was cooled to 85° before entering the tank, on the scales in which it was weighed, weighings being taken before and after each trial.

The temperature of the metal surface of the brake being sensibly the same as that of the effluent water (212°), and by taking the difference in the work absorbed in two trials and the differences in the heats developed, the errors of radiation and balance in the brake were approximately eliminated, and in order to complete the elimination the coefficient of radiation was approximately determined, so that a correction might be applied for any residual differences of temperature as observed, and in the same way with the slope of temperatures. Farther assurance was also obtained by making some trials with the brake naked and others with it covered, so as to reduce the loss of heat to one-fifth; and, in the same way with every circumstance which could affect the result trials, means were taken to vary the circumstances in different series of trials, so as to obtain an estimate of the limits of error. All the appliances were most carefully standardized; and taking all the limits of error into account, the limit of the sum was less than 0·0003.

In all fifty-two trials were included in the final result. Of these

25	with loads on the brake of	1,200	ft. lb. at	70	H. P.
21	"	"	600	"	35	"
6	"	"	400	"	23	"

From these, twenty-five separate determinations were made of the equivalent subject to certain general corrections given below, which gave a mean value 777·91, and from this none of the separate determinations differed by as much as 0·2 per cent., which arranged in eight groups, according to the circumstances under which they were made, the greatest divergence from the mean was 0·05 per cent.

It was found impracticable to eliminate entirely from each determination the losses of heat due to radiation, conduction, leakage of water, etc., and so it was found advisable to determine what these losses were. This information was given by the trials themselves, and the necessary corrections were applied to each separate determination. As illustrating the extent to which the method adopted did eliminate these errors, it is interesting to remark that on the mean value of the equivalent determined, without taking these errors into account, the error was only 0·0192 per cent.

Certain final corrections, which had the same values for all trials, were made to the mean value of J, already given. These were introduced on the following various counts:

I. Length of the brake lever (0·00042).
II. Salts dissolved in Manchester water (0·00003).
III. Air dissolved in water used in the trials (−0·00021).
IV. Reduction of weighings to vacuo (−0·00120).
V. Varying specific heat of water (−0·00005).
VI. Pressure on thermometer bulbs (−0·00057).
VII. Work done against gravity (0·00007).
VIII. Engagement of counter (0·00001).

Their total effect was to introduce a correction factor (1 − 0·00125).

The mean corrected value of the specific heat of water between freezing and boiling points, as measured in mechanical units at Manchester, is found to be 776·94.

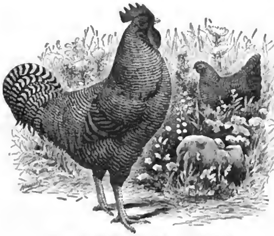
* By Prof. Osborne Reynolds, F. R. S., and W. H. Moorby. Read before the Royal Society, May 26.—Abstract from Nature.

A great boom in autocars is promised in Paris by next spring, the Exhibition year, 1900, being too far off to wait. A company promises to have at least 500 autocars on the streets of Paris by the end of the present year, and about 4,000 before next summer. It is stated that they will be worked by electricity stored in accumulators and the name "chauffeurs" has already been found for the drivers. One translation of that term is "bandits who burned people."

THE STANDARD VARIETIES OF CHICKENS.

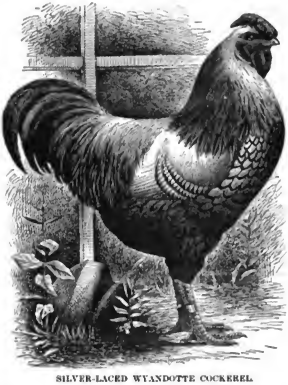
By JOHN MICHELS.*

ONE of the most interesting, and, no doubt, will prove the most popular bulletin issued for farmers by the United States Department of Agriculture, is



PAIR OF BARRED PLYMOUTH ROCKS.

FEATHERS OF BARRED PLYMOUTH ROCKS.



SILVER-LACED WYANDOTTE COCKEREL.

that relating to the standard varieties of chickens in this country, of which there are eighty-seven, besides a large number of promiscuous varieties.

Perhaps the most popular of the varieties, and the best to keep for general purposes, is the barred Plymouth Rock. It is of a grayish white color, regularly crossed with parallel bars of blue black running in straight, distinct lines throughout the entire length of feather. They are hardy, good layers, averaging eight to a pound. This is a practical bird and good for the market, and, at the same time, the most sought after

RED PYLE GAME COCK.

by the fanciers. Some of this variety has pure white plumage.

Next in popularity come the Wyandottes, as they have proved a great success. They were raised from the dark Brahmas, silver-spangled Hamburg and the French fowl Bredas. As their ancestors had feathers on their legs, it would seem to indicate they have Cochin blood in them. They weigh about a pound less than the Plymouth Rock, and are prolific layers, as they generally yield about fourteen dozen eggs a year. There are five varieties, and it is only a matter of taste which is the best. In color some are silver laced, others golden, buff, black, and some white. The average weight, when full grown, is 8½ pounds. The feathers are beautifully marked.

As a contrast to other poultry the tall, commanding figure of the Exhibition Game Cock is remarkable. For a long time Exhibition Games have been a favorite

SILVER DUCKWING GAME COCKEREL.

fowl in this country. By careful breeding for many generations, they have been brought to a high state of perfection. Their beauty is much praised, and their class is always well filled at the numerous shows. It should, however, not be thought that they are unprofitable fowls to keep, but are good for farm purposes. They are, as a class, splendid layers, excellent table fowls and good sitters and mothers.

We now come to the Cochins, of which there are four classes, of which the buff is most bred and popular. Some are pure white, others pure black. The feathering of the legs, feet and even toes is the well known characteristic of this variety, which gives it a rather grotesque appearance; but fanciers consider them very beautiful. They are hardy, good winter layers, but only fairly good table fowls.

This remarkable bird is one of the oldest varieties of poultry. Its ancestors can be traced back to the sixteenth century. They are a medium sized fowl, and the leading characteristic is, of course, the crest, which is composed of yellow feathers, and should rise well up in front, so as not to obstruct the sight, and fall over the back and sides in a flowing, even mass. The smaller the comb the better, and, if wholly removed, it is not considered a disqualification.

The Leghorns are the best known of the egg-producing varieties of the Mediterranean class. The Leghorn hold the same place among poultry that the Jersey hold among cattle. They are lively, active and the best of foragers, and will pick up a great part of their living during the year. They are the best layers, averaging 150 to 200 eggs a year. The eggs are pure white, and weigh about ten to a pound. Altogether, they are the most profitable breeds that can be kept on a farm, the cheapness of their keep allowing the raising of two Leghorns for the cost of one Asiatic. In shape they are graceful, body round and plump, broad at the shoulders and tapering toward the tail.

The Sultans are a recent exportation from Turkey. They were introduced into England in 1854, but reached America several years later. Considering their charac-

FEATHERS OF SILVER-LACED WYANDOTTE.

teristics, they might be classed as Polish, but their feet are feathered and they have a fifth toe. Their beauty is their chief recommendation, as they lay claim to modest usefulness only as layers, for they are too small for table use.

The Japanese bantam is white and is noted for the

* Late of the United States Department of Agriculture.

beauty of the tail, as well as for the graceful shape of the neck and breast.

Yokohama sends us this remarkable variety of fowl. The tail is about a yard in length. The Phœnix fowl is one of the myths of the Japanese religion, and is often seen in Japanese pictures. The Bulletin, from

SULTAN COCK.

which our pictures are taken, was prepared by Mr. George E. Howard, secretary of the National Poultry Association, under supervision of Dr. D. E. Salmon.

THE THEATER OF INSECTS.*

THE first zoological book printed in England was the "Theater of Insects," by Moufet in 1634. The title of the book would suggest that the author, after the manner of old Izaak Walton, was wont to moralize a bit over his studies of natural history. We fancy that he

BLACK-TAILED JAPANESE BANTAM COCK.

saw, as upon the stage, both tragedy and comedy in the lives and ways of the little known insect world.

The theater of insects differs from all other theaters in that its busy season comes during the summer months. Just as in the long ago, historical geology tells us that flowers and insects appeared in the world at the same period of time, so now in early spring the blooming of the first flowers announces the awakening of insect life. If during the last week of the month of May you visit a cold, damp woodland of Northern New England, your attention will at once be arrested by

BACK VIEW OF BUFF COCHIN COCK, SHOWING FULL FEATHERING.

the handsome and conspicuous blossoms of the hobble bush, or wayfaring tree. The large flower buds are formed the previous season, pass the winter wholly naked and open in spring with the appearance of the leaves.

This shrub may be easily recognized by its straggling habit of growth, its drooping branches and the broad flat heads, or corymbs, of flowers of two different sizes. The center florets are small, greenish in color, and in autumn produce bright red berries; while the marginal ones, a single row of which surrounds the corymb, are large, white, and sterile. Their size has been increased at the expense of their power of producing seed, and as their use is to attract the attention of insects, they usually open some days in advance of the inner and smaller florets. But for them, the blossom would easily pass unnoticed amid the budding foliage, as may be easily proved by cutting them off. Since their conspicuousness is useless to themselves but of benefit to the community, they may be said to unconsciously play the part of benefactors.

A sort of barter or exchange is carried on between the flowers of the hobble bush and the insects, by which each is of service to the other. A small quantity of honey, in a thin layer, is secreted by the inner florets, and as insects pass quickly from floret to floret in search of this, their bodies become covered with pollen, and they repay the plant for the food they obtain by effecting cross fertilization. Let us carefully watch the flower on a sunny day and observe how successful it is in attracting insect visitors. I have taken upon it and have now in my collection three species of bees, one butterfly, a small brown species of miller, three hemiptera, five flies and seven beetles, or twenty species in all, a large number for the month of May. Butterflies are rarely met with, for as the honey is fully exposed and not concealed in a deep pit, as in the pinks, the flowers are adapted only to the visits of short-lipped insects such as flies and beetles. Upon the open flowers they can readily obtain both honey and pollen, and in consequence are the most frequent visitors.

In gathering honey from the flowers of the hobble bush there would seem to be no possible danger to insects, and yet they not unfrequently meet with a tragic end. Here lying upon the flat top of the blossom is a dead fly. Lift it up and you will discover how it was killed. The head is firmly grasped by the mandibles of a white spider, which, rather than release its prey, permits itself to be dragged from its hiding place and deposited in your collecting box.

Except for a red lateral stripe on the abdomen, its color closely resembles that of the flowers amid which it lives, and of whose power of attracting insects it has learned to make use for its own benefit. I have never been able to observe this spider in the act of seizing insects, but I believe it catches them while they are sucking honey. A member of this same family of spiders also frequents the pyramidal flower clusters of the hard hack, and I have known of its capturing so large and strong an insect as the hive bee.

Bees puncture the two-lipped tubular flowers of the common skullcap (Scutellaria galericulata). In two instances a narrow slit was observed on the upper side of the curved corolla tube, and in a third case the whole upper portion of the tube was cut away, leaving the lips suspended by a mere thread. The buds while still quite immature are also punctured at the apex, usually on the under side. The piercing of nearly mature buds has been recorded of Lamium album, but never before, so far as known to the writer, of the skull-

SINGLE-COMB BROWN LEGHORN COCK.

BEARDED SILVER POLISH HEN.

* John H. Lovell, in Popular Science News.

cap. The perforation of the flowers of the Labiata by bees is, however, of common occurrence. Both the maxillæ and mandibles appear to be employed, the former for piercing and the latter for biting away the tissue, and both the humble and hive bees are known to make use of the holes in extracting honey.

If, after the manner of certain plants famous in myth and story, the impatiens (fitly, in this respect, named Touch-me-not) could speak, what a protest it would utter! For unknown centuries it has been developing the color and form of its flowers only at last to find its work in danger of being rendered worse than useless by a change in the habits of its bee visitors. It should, however, be mentioned that the flowers in North America are visited by humming birds, and I have also seen another smaller species of bee enter the flower in search of pollen.

COLOR IN ANIMALS—ITS CAUSES AND USES.*

ANIMAL coloration is either structural or useful. The brilliant colors of some of the minnows are of no actual use to the minnows, but due to some structural peculiarities.

Useful colors are such, for example, as cause an animal to resemble its surroundings—escaping its enemies or enabling it better to creep upon its prey.

An object through which light passes practically without absorption is transparent. Reduce or comminute that object to such condition that large quantities of light are reflected, it becomes white. A transparent piece of glass or ice, pounded into powder, looks perfectly white. The light is dispersed and disseminated in such a way that it no longer passes through, and we get the effect called white. Snow pressed into a solid block becomes transparent. We get glacial ice through the enormous pressure of snows accumulated year after year, that at the bottom of the glacier appears as pure, transparent ice. The binding oil globules in the cream break up the light, and we see the milk as white. Water it, and it turns bluish—more or less transparent.

In the white hair of the head we have the transparent shaft, and under the microscope this shaft air always appears black, though the effect to the naked eye is white.

History tells us of human hair turning white in the night. Long ago this was assigned to some acid secretion in the head arising through some tremendous nervous strain. This is wrong. It is probably due to the blood at the base of the hair forcing up air bubbles through the shaft, this producing disseminated light and the effect of white hair.

This power of changing the coloration of the hair can be utilized in a great many cases, as we find in Arctic animals, for a color protection.

Among structural colors we have the iridescence so commonly distributed through nature. The iridescence of the soap bubble arises from the fact that the bubble being very thin, some light is reflected from the outside of the bubble and some from the inside.

A microscopic examination shows the mother-of-pearl shell to be made up of very fine lines so closely put together that the white light is broken up into its prismatic colors, and we get the so-called "play of colors" or mother-of-pearl. Taking a very careful cast of mother-of-pearl shell with very fine lines, the wax will yield the same iridescence as the mother-of-pearl.

Some birds' feathers owe their color to this same cause—as in the iridescent spots on the peacock and the iridescent green color of the trochilus.

The casting of the skin in the case of the snakes is done entire; in the case of other animals, in large flakes or parts of the skin. In the reptilian casting the new and the old skins are separated by a very fine layer of hairs called "casting hairs," that seem to push up the outer skin while the lower one is forming, separating them so that the old will slide off when the process is ready to be executed.

The crabs in casting their shells exhibit the same curious arrangement of casting hairs which under the microscope appear as really worn off; but it is the lines of the bases of these hairs (which are arranged in rows) that in the reptiles break up the light as in the mother-of-pearl and give us the scale. In some cases these casting hairs have been retained in the animal and applied to a totally different object.

The gecko has curiously lobed feet cut up into ridges and each one covered over with microscopic hairs. It is an arrangement that serves as a sucker and is quite common in the animal kingdom. The fish that attaches itself to the shark has the same principle—a series of slats like a Venetian blind that will pull up and cause suction on the object to which it is applied; and these little casting hairs are of great value in holding the feet flat on objects, also to release the feet when it is necessary to let go. These little geckos are thus enabled to crawl all over ceilings and smooth, vertical rocks. They are common at Villa Franca, in the West Indies, and throughout the tropics generally.

The young gecko cannot hold on to upright surfaces until it has shed its first skin, prior to which shedding the casting hairs are lacking.

In a number of cases biliary salts are deposited in the skin of the animal for the production of the distinctive color.

An interesting change of color is going on in the Caucasian race. Russians, Danes, Norwegians and other northern tribes are characterized by light hair and blue eyes; while along the Mediterranean shores and in Southern Asia people have dark eyes. All the light races are gradually going out of existence; that is to say, there is a tendency for the Caucasian race to become dark, and this is probably based on the action of the liver. A northerner living in the tropics tends to torpidity of the liver; the biliary salts are not properly eliminated from the body and commence to be deposited under the skin. On the other hand, in cold climates, the liver is very active and the biliary salts are carried off and not deposited in the skin, hair and eyes; so we have the light, long hair and blue eyes.

Civilized races are producing a tropical climate throughout the year, and even when living in the extreme north live in a temperature of 70 to 80 degrees all the year round. This acts upon the liver, and the liver upon the skin; and these modern conditions are gradually driving out of existence the light haired and blue eyed races.

Some animals change their color at will. The color itself is always there; but by contracting certain of these pigment cells, and allowing others to expand, a temporary change can be effected. The chromatophores from the skin of a frog represent pigment cells. Some contracted and some expanded in different degrees of expansion will grade the animal in color, making it at times dull brown, at others green.

In the case of the chameleon, the chromatophores are supplied with actual muscles, giving them much more powerful and quick control over their color than most other animals. The chameleon can change to the brown of the bark or to the dark green of the leaves of the tree upon which it lives; but in those stories making the chameleon scarlet on occasion the writers have drawn upon their imaginations; because we know the animal could not produce scarlet.

The cuttlefish has the chromatophores very highly developed. Get hold of one of these or a squid on the sea coast before it dies. You can hardly see the spots upon it, some being as large as, others larger than, a pinhead. Irritate the animal, and you will find the spots closing up. It will become pale instantly, almost as soon as your pencil touches the animal.

The sole of the English coast, when placed upon a gravelly bottom, assumes the color of the bottom to a remarkable degree, this being a case of color protection whereby the animal has the power of making itself in exact harmony with its surroundings. Place the sole in an aquarium with light yellow sand, it would turn just that color; as I have often seen in the aquaria at Woods Holl. Take this same individual sole out of the aquarium and put him on a white porcelain plate, the chromatophores will contract down to the very utmost limit and make the animal almost white. The sole's under surface, of course, is always white.

A sole was found to be entirely out of harmony with the bottom over which it lived. Its color would be light when placed on a dark bottom, and dark when changed over a light bottom; and it was found later the animal was blind and there was no correlation between the surroundings and the chromatophores. Other specimens have been blindfolded and proof afforded that the harmonization was guided entirely by the animal's own eyesight.

Color has reference to the general color of an animal, while coloration means the pattern of color upon the animal, as striped or barred. The proteus has lost all the pigment of the skin, and it being transparent, the blood of the animal shines through and gives it a beautiful pink color—in this case a non-significant color.

In excitement, the wattles around the head and neck of the turkey become deep scarlet, due to the rush of blood to these parts, and gives it one of the sexual colors. The blushing on our own faces is due to some nervous emotion, producing partial paralysis of the muscles controlling the caliber of the capillaries, and these, being relieved of compression, becoming enlarged, an excessive flow of blood, with high color, results.

The polar fox has two general colors—white in winter and dark in summer—both very important to the animal. Formerly it was considered this was due to the fact that dark colors part more easily with their heat than do light colors; therefore, the animals dark in color would get rid of their heat; while in the winter the white acted as a non-conductor of heat, thus retaining it within the animal's body. This theory is now abandoned. The change of color is due to the action of environment, and probably is due not entirely to the action of cold.

The dark summer coat of the polar fox is in general harmony with the ground of the rocky Arctic regions where the sun has melted off the snow; the same thing when the animal becomes white and runs over the snow, when it is almost impossible to see it.

The lemming is a rodent common throughout northern Europe, Asia and North America. In Sir John Ross' northern expedition he kept a lemming in the cabin for a long time in winter. The animal retained its summer pelt of dark brown color in harmony with the rocks upon which it lived. In February he placed it in a cage on deck thirty degrees below zero. Next morning its cheeks and shoulders were patched with white, and at the end of the week it was nearly all white. The hair itself had actually turned white, and I suppose there was no reason to doubt the fact that it was due to the forcing in of air bubbles through the shafts of the hair, breaking up the light. Later on a growth of white hair came out from below, gradually replacing the hair that had been changed so suddenly. The cold of the winter really produced this white hair for the protection of the skin.

The ptarmigan displays this dual coloring, being snow white in winter and almost indistinguishable in the snow, while the summer-plumaged ptarmigan can be within two or three feet of the hunter and invisible. The male is quite conspicuous, but he is very shy and keeps away from his enemies. I remember gunning once in Greenland when some of these ptarmigans were located, and, after waiting awhile for a shot, we finally fired at the group, when right around us, within six feet, six of them flew up, unnoticed before because of the perfect harmony of their coloration with the ground. In watching those we were going to shoot, it was sometimes difficult to see them actually, but as soon as they were shot the white feathers underneath were thrown up and they were then very conspicuous on these dark rocks. These were cases of protective coloration.

The caddis worm, the larva of the dragon fly, abundant in the waters of our parks, wraps itself in tubes made out of particles of sand; so that while it crawls around on the sandy bottom we cannot see it.

The crabs will do that, and not fasten the substances to their shells always, but will actually put them on. The common spider crab of our coasts has its outer covering rough and covered with peculiar hairy hooks and spines; and the animal will put seaweeds upon itself. If one found covered with green seaweed be placed in an aquarium with reddish brown seaweed, it will strip itself of the green and put on the brown, so as to harmonize itself with its surroundings.

Antennarius—a fish common in the Sargasso Sea—is in actual color brown, resembling gulfweed, and spotted, and has peculiar long tentacles or filaments running off from the body, which resemble the filaments peculiar to the gulfweed. It is one of the most beautiful cases of mimicry in color and form that we know of among fishes.

We find color mimicry even among snails; one species in Cuba affording a great variety of blues, reds, blacks and greens, more or less arboreal, living upon different colored fruits, as yellow or red bananas or pommes de terre—upon green fruits and green leaves. In all there is a thorny, hairylike substance on the outside of the shell which accumulates mud; so that the animal looks like a little ball of mud and is very inconspicuous when first detected.

As a rule, arboreal snails are green. The green ones among the Philippine Islands are arboreal right straight through, and resemble the foliage upon which they live.

Some snails, not being protected in other ways, have another curious form of protection, namely, teeth in the mouth of the shells. Mr. Pilsbry, of the academy, has concluded that these teeth are for the purpose of keeping out carnivorous enemies.

There are snails actually resembling thorns. This variety remained for a long time undiscovered until someone, carefully examining some of the bushes, noticed the fellows walking around upon the branches.

Animals, again, will have some part of the body that they can well spare brilliantly colored for the attraction of some enemy; this part, when grasped, being readily detached from the body, and, while losing the part, the sufferer escapes with its life.

A certain snail has upon the end of its tail a bright red spot, which comes off almost on touching it. A bird seeing this will seize the only object it sees, because the animal will be on a green leaf; the snail will part with this brilliant piece of coloring and drop to the ground and thus save its life. One authority in taking a large number of these snails found ten per cent. had lost their tails in this way to their enemies.

Lizards likewise lose their tails to their enemies and thus save their alter ego.

The squirrel has a very conspicuous tail. The Germans have dubbed the animal Eichhoernchen, "the little horn on the oak tree." A squirrel on the run has its tail spread out behind it. An enemy seizing this will get nothing but a bunch of hair, the skin at the tip of the tail coming off very easily with its tuft of hair, leaving the main brush still in the possession of the animal.

Another peculiar coloration among animals but recently pointed out by Wallace is the so-called warning colors. New examples are coming to light almost daily. One of the most conspicuous examples is the skunk, Mephitis Americana, than which probably there is no other animal on the American continent more conspicuous, and none to which we would more readily yield a clear coast. A peculiar secretion that can be voided by this animal is intensely offensive, but as long as the animal is left alone this is not put into operation. The animal is very conspicuous in the dark; and with its jet black underneath portion and its bright bands of white, it carries a signal flag to keep out of the way.

The tree toads, living on leaves, are green in color; while those living upon the ground are dull, like the clay and dirt of their habitat. In the tropics, tree frogs and ground frogs are nocturnal, almost without exception, and all of them have protective coloration.

There is a little diurnal frog, that leaps about perfectly fearlessly through the tropical woods, with brilliant blue coat and crimson breeches; and he is there in large numbers. His devourers are lizards and birds. A naturalist brought some home to his garden, and tried to feed them to his ducks, which would not have anything to do with them. Some pieces of meat, the size of these frogs, were fed by hand to the ducks, and, during the operation, a frog was substituted for the meat, and the exotic frog thus introduced into the mouth of the duck, which ran around the yard shaking his head as though he had received some very disagreeable acrid dose from the animal.

Some of the snails are extremely conspicuous on certain rocks. Voyagers down the Riviera have noticed a pure white snail attached to the rocks. A snail collector in Central America, having to use both hands in climbing the rocks whereon rested a conspicuously colored group of snails, seized the snails in his mouth, but could not keep them there. They were so very bitter and caustic he was obliged to throw them out. Most snails can be retained in the mouth without disagreeable consequences; but these snails upon the rocks undoubtedly protect themselves against their enemies, the birds, by a flavor they cannot stomach.

Since the creation there has been ceaseless activity among the carnivores and herbivores—among the former, to eat the latter; among the latter, to get out of the way. We have developed in the carnivores craft and strength; in the herbivores speed, as in the zebra.

There is nothing in the world more conspicuous than a zebra. And yet Baldwin, one of the most trustworthy naturalists, says that in his travels in Africa, on bright, starlight nights, the zebras would come so near that he could hear them breathing and yet could not see them. If the zebra's bands were any broader, it would appear as a black mass; and if any lighter, as a light mass. As it was, so did they harmonize with their surroundings it was impossible to locate them.

Cummings, in his travels in Africa, speaks of the giraffe, an animal almost as conspicuous as the zebra. Giraffes seen in the zoological gardens, back of grates, with ugly bars around them, stand out very conspicuously; but a herd of giraffes in the forest, with the light passing through in different ways, the sun spots here and there and the tall necks of the giraffes, it is impossible to see them; and Cummings says time and time again he has had a herd of giraffe browsing in the edge of a forest pointed out to him by his native hunters, and even with the aid of a telescope he could not see them himself. At yet other times he has taken the blasted tree trunks for the necks and bodies of giraffes; but found his mistake on closer approach.

The Bengal tiger, seeking its prey among the jungles, exactly harmonizes, in its upright bands of color, with the lights and shadows around it.

The leopard in the forest, resting upon the trunks and limbs of trees, with the play of lights and shadows from above, has in his own skin a very good imitation of the sun spots.

* Condensed from a lecture by Dr. Benjamin Sharp, at the Academy of Natural Sciences, Philadelphia.

Wild hogs are striped, and when threatened will squat among the leaves and become very inconspicuous.

The tawny color of the lion harmonizes with the barren wastes upon which it lives.

The bird known as the creeper, native among us, greatly resembles in color the bark of the trees.

The color of killdeers, both young birds and nests, closely resembles that of the stony ground on which they live.

The rabbit is very inconspicuous upon the ground at rest until he starts up and shows his white "cotton tail;" and this brings us to the recognition marks distributed among the gregarious animals, and to which Wallace has called the attention of naturalists.

Very characteristic recognition marks among the animals are those that are of such a nature as to keep the herd together. The peculiar white patch about the tail of a deer is one of these recognition marks. Hunters know that this can scarcely be seen if the animal is not frightened; but when, being shot at, it runs away, this is one of the most conspicuous features of the deer. The other members of the herd, seeing this recognition mark in the escaping animal, know the danger and take flight.

There is a peculiar white and very characteristic marking about the eye of one of the gazelles; and all these animals living in Africa and on our Western plains have more or less of these so-called recognition marks. The Rocky Mountain antelope has the recognition markings in the head.

We find birds also very well marked; for example, the white bands on the tail of the whippoorwill, which bands are not seen when the animal is not frightened or moving.

Mimicry was the first term used in these peculiar adaptations of color to surroundings. Originally the term mimicry meant a resemblance of the animal to its surroundings, be they animate or inanimate; but now we restrict "mimicry" to where one animal mimics another animal. This is very clearly shown in the humming bird moths, which have been repeatedly shot by the naturalist Wallace in mistake for humming birds. The humming bird moth is one of the sphinxes, in which the tongue, instead of being rolled up, is kept out straight, resembling the bill of the humming bird; while at the end of the abdomen a number of hairs run out and resemble, to a certain extent, the bird. The flight of the sphinx closely resembles that of the humming bird; and for two such naturalists as Bates and Wallace to be continually making these mistakes proves the resemblance and shows why a bird, feeding upon insects, would let a humming bird moth go, deeming it a humming bird.

In the East Indies, a cuckoo mimics a hawk in both size and color, so that one is often mistaken for the other.

The coral snake occurs in our Southern States and in Trinidad, being poisonous. There is a snake that mimics the coral snake that is perfectly harmless. Some of the people insist that all of the coral snakes are poisonous; others, who have had experience with the form mimicking the coral snakes, say they are not.

As to the leaf butterfly, in old books we read how bushes in India have flying leaves. The leaves would come off and fly around. Wallace in his work says: "In the East Indian archipelago we would see these butterflies alight upon a bush and thoroughly disappear." They simply resembled in form and color the leaves of the bush upon which they rested.

Caterpillar and cocoon found in this locality will resemble the bark of the trees upon which they rest. Doctor Skinner, entomologist of the Academy of Natural Sciences, relates how once finding one of these caterpillars and having at hand nothing to collect or carry insects, he went off a short time to get his materials, and on returning for this caterpillar, though he searched over an hour and though it probably had not moved over a half inch, it was so exactly like the bark of the tree he could not find it.

Not only does the caterpillar have this protective coloration, but also the cocoon, resembling the bark of the tree upon which it is spun. The butterfly, also, to a certain extent, is concealed in this way.

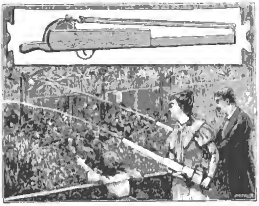
CONFETTI AND SERPENTINES.

DURING the Parisian carnival and midlent, confetti and serpentines have full sway. Although the invention is of recent date, it is making up for lost time. How many confetti and how many serpentines? According to the taste of some, there are altogether too many. Upon the boulevards and the large streets they form a continuous rain. In the evening, the confetti are found in layers of from half an inch to an inch and a half in thickness at certain points, and the serpentines are seen involving the trees in their multicolored meshes. In the sun the effect is charming, but the next day, if it happens to rain, the aspect is mournful.

The confetti having come into fashion, it follows as a necessary consequence that an endeavor has been made to derive as much advantage from them as possible. The spirit of invention is not wanting in Paris. People, getting tired of throwing them by the handful from the balconies of houses, have often, in order to expedite matters, emptied whole bagfuls of them upon the heads of the crowd. It is a very heavy circumscribed rain, but it does not last long enough. On the Boulevard de la Madeleine we have seen a dozen large bagfuls exhausted in this way in five minutes. This being wasteful, an endeavor was made to do better. Then the confetti cane made its appearance. This new air gun was a success, because the little disks are thrown to a distance and fall in a colored shower upon the floats and emblematic figures. It is impossible to escape the shot, for the weapon is accurate, and the projectiles, shot with force, fall gracefully upon the object selected as a target. At a distance of thirty feet one is as sure of covering his chance enemy as if he had fired an explosive shell. For the fetes of Nice and Cannes we shall evidently have some day a flower air gun, so that it will be possible to throw bouquets and perfumed petals to a distance. In the meanwhile, Parisians are firing confetti with the cane in fashion. This has the appearance of an ordinary bamboo walking stick. The silver head is unscrewed and the owner takes from his pocket a long cartridge loaded with a respectable number of colored confetti, which he introduces into the cane. With a rod he then rams home the cartridge, which causes a spring to bend. After this he tears and removes the paper covering. The weapon is now loaded. Toward the middle of the cane there is a trigger button. The "Queen of Queens" is passing. The button is pressed, the spring is freed and the entire supply of confetti is fired at once like a ball. A wheat sheaf jet forms at a distance of from 25 to 30 feet and descends like a colored rain upon the royal float, which becomes covered with emeralds and sapphires! There are persons who fire a hundred cartridges a day in this manner, much to the amusement of idlers. The confetti cane has proved a success.

In another form the same system has found its way into restaurants, to the family table, and especially into private rooms. A party has dined well and every one is merry; it is time for the champagne. The glasses await the bottle with its golden neck. The wire is cut, the cork starts and the foam is about to appear, when, to the surprise of all, a bouquet of confetti, instead, escapes with noise from the bottle, strikes the ceiling, falls back upon the table and covers it with petals of every hue. This is "champagne aux confetti." The stratagem may be imagined. As with the cane, the bottle has been loaded with a cartridge, and, through pressure upon a well concealed spring, the cork and confetti have been started.

Finally, in order to exhaust the list of novelties in this line, it would be unjust not to mention the "Spirobolus," a sort of serpentine shooting crossbow. This is an out of door apparatus that has its devotees. The serpentines thrown by hand do not go very far, and, in most cases, fail to hit the mark. The idea occurred to make the firing sure and to give it true precision. As if by magic, the spirobolus unwinds the roll of paper to its full extent in the twinkling of an eye. The effect of the unwinding of this colored paper band is very pretty. The system is simple. The roll is placed in a groove formed in the stock of the instrument, which is provided with a strong rubber cord that engages with a powerful spring. Upon a trigger being pulled the cord is freed, and the spring, in relaxing, sets the roll in motion. To this effect the roll is provided externally with a band of cloth which is attached to a fixed point, and which enters small points placed in the groove of the instrument. One of the ends of the serpentine is thus attached. The propulsion causes the unwinding of the roll, which continues paying out the paper until the other extremity is reached. It is unnecessary to say that firing with the spirobolus must not be done at close range, since some one might be hit and harmed by the roll before it was entirely unwound. —*La Nature.*



SPIROBOLUS FOR FIRING SERPENTINES.

CANE FOR FIRING CONFETTI.

CONFETTI FIRED FROM A CHAMPAGNE BOTTLE.

THE CULTIVATION OF CHICLE, FOR CHEWING GUM, IN MEXICO.

CHICLE chewing gum is principally extracted from the chico-zapote, the chic-zapotl of the Tarascans, says the Journal of the Society of Arts. Other plants are also chicle producing, such as Amate, growing wild in the district of Jalapa, Tabasco; Caimito, cultivated and found wild in the district of Jalapa, in the municipalities of Cunduacan and Cardenas, Tabasco, and in the canton of Jalapa, Vera Cruz; Cajon de mico, found wild in the municipality of Macuspana, Tabasco, and in the department of Comitan, Chiapas; Copo, found wild in the municipality of Frontera, Tabasco; Chichivisha and Matapalo, found wild in the municipality of Zanatepec, Oaxaca; and Sletilio or Yoyote, indigenous to the districts of Cunduacan, Yacajuca, and Huimanguillo, Tabasco.

Sir Henry Dering, H. M. Minister at Mexico, in a further report upon the vegetable products of Mexico, says that chico-zapote (Achras sapota of Linnæus) is the most abundant and important of the gum producing trees. This tree is found in many districts, and it is cultivated in the districts of Chonpam, Cincatlan, and in the municipality of Zanatepec, Oaxaca; in the districts of San Juan Bautista, Jalapa, Cunduacan, Cardenas, Nacayuca, and Huimanguillo, Tabasco; in the districts of Jalapa Cordoba, Minatitlan, Vera Cruz, and in parts of Morelos and Michoacan.

Chico-zapote belongs to the family of Sapotaceæ, and two kinds, the red and white, have been found in the dense forests of the above mentioned regions. The white zapote produces more gum than the red kind—as high as 6 pounds to the tree—and the white is generally taller, being 12 meters in height, while the red zapote has a thicker bark, from 8 to 10 meters high and seldom yields more than 3 to 4 pounds of chicle. The leaves of both trees are somewhat elliptical, and on young branches or shoots they are rather numerous. The fruit is spherical, sometimes 2 and 3 inches long; its edible matter is white, and tastes like the pear, and the seeds are two or three in number, of a dark brown color, flat, and irregular in shape.

A warm, moist climate is necessary for the successful growth of the tree if large amounts of fluid are expected. Higher than latitude 22° N. it will not grow at all, and north of Vera Cruz city it will not do well in the mountains above 2,000 feet. However south of 19° N. latitude it is cultivated at altitudes as high as 3,500 and 4,000 feet above sea level, yet it will thrive best at elevations between 150 and 1,200 feet even in these latter regions.

The best soil adapted for its cultivation is that occurring in valleys and undulating lands along the river meadows at the foot of the mountains. In the Tuxpam and Papantla valleys, especially in the dales adjoining the Pantapec, Cazones (San Marcos), and Tecolutla Rivers, splendid lands suitable for its cultivation can be found.

The zapote can be propagated from cuttings, suckers and layering, but the tree grows readily from the seed and that system has been adopted by those who plant it. Nursery beds are prepared in the usual manner in a half shaded space close to a stream. The seeds are sown in October and November, and sometimes in July. When the seedlings are 18 to 24 inches high, they must be transplanted.

As the tree is a hardy one, the expenses of keeping the zapote plantation clean are small. One or two light weedings a year is all that is necessary. At the fourth or fifth year after transplanting the tree may be tapped, but it is best to wait until the sixth or seventh year, or when they are 12 to 15 inches in diameter, wherein better results may be obtained. The tree lasts over 100 years, and then, or before, its fine wood can be utilized for the manufacture of first class furniture, or for durable timber. The gum is produced from the leaves, fruit, and bark of the tree. From the fruit it is extracted in the months of March and April, before the fruit becomes ripe. When gathering the fruit, the stem is allowed to remain on it, but subsequently taken off to admit of the juice running out. This is collected in a shallow vessel, allowed to solidify, washed in warm water to collect and clean it, and then boiled down to evaporate the water, set aside to cool, and lastly formed into blocks to be marketed. Three thousand two hundred zapote pears produce one pound of gum.

The fruit is also sold for about a cent apiece in Vera Cruz, Puebla, Oaxaca, Orizaba, Mexico, Guadalajara, and other large cities, and has recently been exported to the United States. In September and October the gum is extracted from the leaves. The process is the

same as that of the fruit, and the yield alike. After the rainy season is over, generally in October, the trees are tapped once every year.

The custom of the natives, the chicleros, is to get up the tree, to a distance of about 40 feet, make three diagonal cuts by a double oblique blow of the machete on either side of the tree, and have the wounds join at their lower ends. A shallow tin vessel is tied on to the tree below the wounds to collect the juice. Then the operator leaves this tree and taps another. He performs this operation in twenty minutes, and it takes three-quarters of an hour for the tree to bleed itself. One man will tap from twelve to sixteen trees per day, each producing from 3 to 6 pounds of juice. This is collected in gourds holding 12 pints, and heated in an iron pot until it boils up, when it is stirred with a stick quickly and continually until the foaming gum subsides, and has been reduced to half. When cool it is washed in water and formed into blocks, marquetas, of 2, 4, 6 and 12½ pounds.

Sir H. Dering says that the present system of tapping could be improved, and that the juice should be strained before being boiled down. The expense of a plantation of 100 acres to the time of production (six years after transplanting) is as follows: Clearing the land, from $600 to $800; nursery, $250; planting, $600; weeding six years, $1,200, and fencing, $50. At an additional expense of 10 per cent. a patch of Indian corn can be raised, and the proceeds from it will more than meet the expense of the plantation.

In the Tuxpam valley it costs from $5 to $7 per arroba of 25 pounds to gather and clear the gum—that is, by contracting the work with the experts (the chicleros); but by hired labor there and in Papantla, Misantla, Esperiol and Zamovra Gutierrez the cost will only be from 10 cents to 15 cents per pound. In Campeche and Michoacan the cost is as high as 20 cents per pound and in parts of Oaxaca, Vera Cruz, and Tabasco, from 4 to 25 cents a year per tree is paid for the privilege of tapping trees on private lands. The production of chicle for the year 1892, the latest for which the particulars are available, was as follows: In the district of Carmen, Campeche, 1,380,740 kilogrammes, valued at $12,000; in Oaxaca the districts of Juquila and Tuxtepec reported 1,150 kilogrammes each, valued at $950; in Puebla, the district of Huauchinango produced 1,300 kilogrammes, valued at $600; in Tabasco, the district of Balancan yielded 16,108 kilogrammes, valued at $11,200; and the municipalities of Zamora, Gutierrez and Tecolutla, Vera Cruz, reported 3,445,434 kilogrammes, valued at $1,824,000. Sir Henry Dering says that the price of chicle gum at New York City was, at the date of his report (July 18 last), 45 cents gold per pound.

THE POPULATION OF RUSSIA.

THE results of the first one-day census, which was made throughout the width and breadth of the Russian empire on February 9 last, were expected with great interest, says Nature. The last census was made in 1851, and a partial one in 1858, and yet it was not a census proper, for the local police authorities on the spot merely made lists of the permanent residents and taxpayers in each locality. After much preparatory work, it was decided to make, this year, a "one-day census:" that is, in the lists which had to be made for each house in each locality, all those persons who spent the night in a given house and in a given locality on February 9 (or about that date in the villages), had to be mentioned, whether they were permanent residents or not. It was quite a novel experiment, which was looked at with little confidence; but the vice-president of the Russian Geographical Society, who had had already a great deal of experience with such censuses as they were made, since 1870, in separate big towns (in these censuses the illiterate population filled their lists, as a rule, admirably well), insisted upon the new method being accepted. The census was organized under his guidance, and seems, so far as can be judged, to have been quite successful. The items, obtained from all the local committees, partly by telegraph—with the exception of some parts of the province of Yakutsk—are now published; and the population of the empire appears from them as follows: European Russia, 94,188,750; Kingdom of Poland, 9,442,590; Grand Duchy of Finland (Finnish yearly census), 2,527,801; Caucasia, 9,723,553; Siberia and Sakhalin, 5,731,732; the Kirghiz Steppes, 3,415,174; Turkestan, with the Transcaspian region and the Pamirs, 4,175,101; Russian subjects in Bokhara and Khiva, 6,412; total, 129,211,113. The corresponding figures, in 1851, were: European Russia, 52,797,083; Poland, 4,852,055; Finland, 1,636,915; Caucasia, 4,436,152; Siberia, 2,487,184; Steppes, 1,239,654; total, 67,380,645. It may thus be said that, although the percentage of births is very high in Russia, it took nearly fifty years for the population to double.

An English writer about Russia made, some time ago, the remark that Russia suffers from apolism, that is, from a want of towns. This want has lately very much disappeared. There are now in the empire no less than 19 towns having a population of more than 100,000 (out of which two in Poland, two in Caucasia, and one, Tashkend, in Turkestan); 35 towns with populations from 50,000 to 100,000, and 69 towns with populations of from 25,000 to 50,000. St. Petersburg has already attained the figure of 1,267,023, and Moscow approaches the million (988,610).

It is worth mentioning that no less than 200,000 persons took part in the census; very many of them were volunteers, who were recruited among the students of the universities and the high schools.

A Roentgen society has been formed, with Prof. S. P. Thompson as the president, says Nature. The intention of the founders is that the society shall occupy a position between those devoted purely to medicine, to physics, or to photography. Some of the members will study the sources of the Roentgen rays, others the applications; some the induction coils, others the tubes and the various forms and adaptations of the apparatus used in the production of the rays. Roentgen photography has been found serviceable in so many branches of scientific investigation that the society appeals to a large constituency for support. It should be the means of increasing the efficiency and applications of the rays, and should also be of assistance to surgeons and others who have entered the new field of work without previous training in physics.

THE

Scientific American Supplement.

PUBLISHED WEEKLY.

Terms of Subscription, $5 a Year.

Sent by mail, postage prepaid, to subscribers in any part of the United States or Canada. Six dollars a year, sent, prepaid, to any foreign country.

All the back numbers of THE SUPPLEMENT, from the commencement, January 1, 1876, can be had. Price, 10 cents each.

All the back volumes of THE SUPPLEMENT can likewise be supplied. Two volumes are issued yearly. Price of each volume, $2.50 stitched in paper, or $3.50 bound in stiff covers.

COMBINED RATES.—One copy of SCIENTIFIC AMERICAN and one copy of SCIENTIFIC AMERICAN SUPPLEMENT, one year, postpaid, $7.00.

A liberal discount to booksellers, news agents, and canvassers.

VICTORIA'S JUBILEE.

THE so-called "Diamond Jubilee" of Queen Victoria, which commemorated the sixtieth anniversary of her accession to the throne of Great Britain, was certainly the most splendid spectacle of modern times and was the most imposing outward display of the political, social and military factors of modern civilization which the world has witnessed. It was not only a personal tribute to the aged Queen who has reigned so well, but it was a manifestation of the imperial power of this great nation. To those who believe in the great destiny of the English speaking race that already dominates so large a part of the world, this demonstration has more than national importance and is vastly sig-

THE QUEEN'S JUBILEE—ILLUMINATION OF WINDSOR CASTLE ON JUNE 18.

nificant. Victoria's reign has been concurrent with the era of greatest expansion of the English speaking race. When the long reign is carefully analyzed, it will be seen that Thiers' famous saying, "The King reigns but does not govern," is not entirely applicable in this case. Victoria has been many times instrumental in shaping policies which have redounded to the credit of England and she has steered clear of the many blunders to which monarchs are so prone. Victoria's wisdom leads her not to seek to govern so much as to guide, and her gracious presence has often moderated the asperities of party conflict. Certainly no other ruler has done so much to make a proletarian outbreak like that of the French Revolution impossible.

The celebration of the "Diamond Jubilee" began on Sunday, June 20, with the holding of thanksgiving services throughout the kingdom, and everywhere, from a huge fair. The city was magnificently dressed with flags, bunting, and other elaborate decorations, and even in the smoke soiled back streets off the line of the route could be seen little union jacks sticking out of the top corner of a broken window of some cheap tenement. The whole city had to be seen before the meaning of the Jubilee could be appreciated in the gross.

Every available nook and corner was taken up with seats for spectators. They brought fabulous prices. In some cases the sum received was sufficient to entirely rebuild the structure. These stands were built with true British solidity, so that there were no accidents whatever. Just before the Jubilee prices for seats dropped to a wonderful extent, and many of the speculators found they were ruined. One gentleman, who some weeks before had paid \$5,000 for a room with two windows, found that they would not fetch over \$500. Bridge Road, Westminster Bridge, Parliament Street and the Mall to Buckingham Palace. First came the Royal Horse Guards, then the colonial troops. The troops consisted of Canadian Hussars, Dragoons, and Mounted Police, New South Wales Lancers and Mounted Rifles, with their graceful felt hats and brown boots, Victorian Mounted Rifles, New Zealand Mounted Troops, Queensland Mounted Rifles, Cape Mounted Rifles, South Australian Lancers and Mounted Rifles, Natal Mounted Troops, Natal Carabiniers, Umvoti, Natal and Border Mounted Rifles, Mounted Troops of Crown Colonies, Zaptiehs from Cyprus, Trinidad Mounted Rifles, and a few Rhodesian Horse. The colonial troops were very interesting and were well received, and gave an excellent idea of England's imperial possessions; then came various portions of the Naval Brigade and the high officers of the army. The

THE QUEEN'S JUBILEE—GROUP OF ENGLISH SOLDIERS AND NATIVE COLONIAL DETACHMENTS, INCLUDING POLICE OF BORNEO, POLICE FROM CYPRUS, AND HAOUSSAS FROM THE AFRICAN GOLD COAST.

St. Paul's Cathedral to the humblest village chapel, the people met to pray for Her Majesty. A private service was held in St. George's Chapel, Windsor Castle, which was attended by the Queen and the members of the royal family. Her children embraced her after the service. Public service was held in the chapel in the afternoon, a chorus of five hundred voices giving Mendelssohn's "Hymn of Praise." A special service was held in St. Paul's Cathedral, London, in which the diplomats, special Jubilee envoys and judges in their robes of state attended.

Continuous services were held in many of the churches throughout the day. It was the strangest Sunday ever seen in London. London is ordinarily the most dreary place imaginable upon the Sabbath; so much so that Americans, at least, are always glad to get away from its depressing influence; but on this occasion the route that was to be traversed by the royal procession resembled Desirable seats cost from \$25 to \$150 and even more, and everything else was in proportion. The commercial aspect of the Jubilee is, perhaps, the only disagreeable feature connected with it, and it was very hard to see how it could have been avoided.

The Queen made a triumphal progress from Windsor to London, where she rested at Buckingham Palace. In the early morning of Tuesday, June 22, the great day of the royal procession dawned cloudy and still, but very shortly before the Queen's carriage became visible, in the courtyard of Buckingham Palace, the dark clouds were thinner and less ominous. The rest of the morning and afternoon was bright and sunshiny. In brief, the route of the procession was from Buckingham Palace, around Constitution Hill, down Piccadilly, St. James Street, Pall Mall, the Strand, Fleet Street to St. Paul's, then by way of Cheapside, London Bridge, Borough High Street, Borough Road, Westminster total number of troops employed in the procession as guards of honor and in lining the streets was 46,943.

Punctually at eleven the starting gun in Hyde Park was fired as a signal that the Queen had entered her carriage. Her progress toward St. Paul's Cathedral, where the colonial procession had already gone, was made with few delays. Various detachments of soldiers and representatives of the navy led the way. After the regular troops had passed came the naval and military aides-de-camp to the Queen. Then the pageant became more gorgeous than ever, the foreign naval and military attachés glittering in their many colored uniforms; ambassadors came next, and now the excitement was most intense as the Queen and her escorts appeared. Perhaps there was never assembled in public a more august body of dignitaries. There was an escort of thirty-six English and foreign princes on horseback, riding in threes; an Indian escort of twenty navy offi-

cers and cavalry regiments followed; then came the supreme moment for which the many millions had been waiting. Field Marshal Lord Wolseley, Commander-in-Chief of the British army, rode by alone, and then there were seen the cream colored horses which were famous throughout the empire drawing the carriage in which sat the sovereign. The enthusiasm knew no bounds. It could, perhaps, be described adequately by saying it was an avalanche of sound. It was difficult to believe that seventy-eight eventful years had passed over the Queen's head. Her Majesty was seated opposite the Princess of Wales and the Princess Christian. The Prince of Wales, the Duke of Connaught and the Duke of Cambridge were by her side as outriders; behind followed the royal standard, grooms and equerries. Last of all come the Royal Irish Constabulary and a squadron of the Horse Guards. When the Queen's carriage reached Temple Bar the Lord Mayor was waiting to receive Her Majesty to render official homage and to present a pearl sword of state. She spoke a few words in reply to the address of the Lord Mayor and the procession moved on to St. Paul's.

As the Queen approached St. Paul's Cathedral the Archbishops of Canterbury and York, with a numerous train of clericals, emerged from the west front and stood upon the steps, where they awaited the arrival of Her Majesty. Immediately, as the Queen's carriage was drawn up, the choir intoned the "Te Deum," after which the Bishop of London offered a prayer. The Archbishop of Canterbury then pronounced the benediction, after which the choir sang the Hundredth Psalm. This service is an interesting contrast to that which occurred when the girlish Queen had been anointed in Westminster Abbey, sixty years before. The ceremonies at St. Paul's were so interesting that we cannot refrain from giving Mr. G. W. Steevens' pen picture of the event which he gave in the Daily Mail.

"Riding three-and-three came a kaleidoscope of dazzling horsemen, equerries, aides-de-camp, attachés, ambassadors, and princes, all the pomp of all the nations of the earth—scarlet and gold, azure and gold, purple and gold, emerald and gold, white and gold—always a changing tumult of colors that seemed to list and gleam with a light of their own. It was enough. No eye could bear more gorgeousness; no more gorgeousness could there be, unless princes are to clothe themselves in rainbows and the very sun.

"The prelude was played, and now the great moment was at hand. Already carriages were rolling up, full of the Queen's kindred, full of her children and children's children; but we hardly looked at them. Down there through an avenue of eager faces, through a storm of white, waving handkerchiefs, through roaring volleys of cheers, there was approaching a carriage drawn by eight cream colored horses. The roar surged up the street, keeping pace with the eight horses. The carriage passed the barrier; it entered the churchyard; it wheeled left and then right; it drove up to the very steps of the cathedral.

"We all leaped up. Cheers broke into screams, and the enthusiasm swelled to delirium. The sun, watery until now, shone out suddenly, clear and dry, and there and there and there was a little, plain, flushed old lady, all in black, with a silver streak under her black bonnet, and with a simple white sunshade, sitting quite still, with the corners of her mouth drawn tight, as if she was trying not to cry. But that old lady was the Queen, and you knew it. You did not want to look at the glittering uniforms now, nor yet at the bright gowns and young faces in the carriages, nor yet at the stately princes, though by now all these were ranged in a half circle round her.

"You could not look at anybody but the Queen, so very quiet, so very grave, so very punctual, and so unmistakably every inch a lady and a Queen.

"It was almost pathetic, if you will, that small, black figure in the middle of these shining cavaliers, this great army, this roaring multitude, but it was also very glorious.

"When other kings of the world drive abroad, an escort rides close at the wheels of their carriages. The Queen drove through her people quite plain and open, with just one soldier at the curbstone between her and them. Why not? They are quite free. They have no cause to fear her. They have much cause to love her. Was it not all for her—gala trappings of the streets, men, horses, guns, and the living walls of British men and women? For the Queen summed up all that had gone before—all the soldiers and sailors, the big limbed colonials, and the strange men from unheard of islands over sea.

"We know now what that which had come before all stood for. We knew as we had never known before what the Queen stands for. The empire had come together to revere and bless the mother of the empire. The mother of the empire had come to do homage to the one being more majestic than she.

"There were the archbishops, bishops and deans in gold and crimson caps and white, orange and gold embroidered vestments waiting on the steps. There, through gaps in the pillars and scaffoldings, you could see all her ministers and great men, a strange glimpse of miniature faces as in some carefully labored picture, where each face stands for an honored name.

"All stood, and the choir sang the 'Te Deum.' Next rose up a melodious voice intoning prayers. The Queen bowed her head and then the whole choir and the company outside the cathedral and the whole company in the stands, at the windows, on the housetops, and away down the street, all standing, all uncovered, began to sing the Old Hundredth Psalm, 'Come ye before Him and rejoice.'

"The Queen's lips were tight, and her eyes, perhaps it was fancy, looked dim; but then 'Three cheers for the Queen!' and the dean, pious man, was wildly waving that wonderful crimson cap, and the pillars and roofs were ringing as if they must come down. Then 'God Save the Queen,' a lusty peal till you felt drowned in sound.

"The Queen looked up and smiled, and the Queen's smile was the end and crown of it all, a smile that broke down the sad mouth, a smile that seemed half reluctant, so wistful, yet so kind, so sincere, so motherly."

The colonials fell in behind the royal procession after leaving St. Paul's. A brief stoppage was made at the Mansion House by the Lord Mayor's wife, who presented a bouquet to the Queen, and here Her Majesty dispensed with the attendance of the Lord Mayor, who had accompanied her from Temple Bar. The procession then continued to London Bridge, and thence along the streets on the southern side of the Thames. It reached Buckingham Palace at 1:40 P. M., twenty minutes before the programme time. Before the return of Her Majesty to the palace, she lay down for an hour, and spent the rest of the afternoon in the garden. She bore the fatigue exceedingly well. The enthusiasm of the British people for several days was unbounded, and the splendid display of sea power—the greatest the world ever saw—on June 26, at Spithead, was the other crowning feature of this memorable occasion.

Our engravings, for which we are indebted to L'Illustration, represent the military tattoo at Windsor before the departure of the Queen, and the colonial soldiers in the procession, and the procession passing through Whitechapel.

THE QUEEN'S JUBILEE—COLONIAL TROOP PASSING THROUGH WHITECHAPEL.

INCREASE OF THE DRYING POWER OF OILS.

By A. LIVACHE.

THE principal factors which increase the power of fixing oxygen of a siccative oil such as linseed are, first, the degree of purity of the oil; secondly, the time which has elapsed since its extraction; thirdly, the conditions under which it has been kept; fourthly, heat; fifthly, the addition of certain substances.

1. The Degree of Purity of the Oil.—When the oil has been extracted by the press, it contains water and impurities, and it is evident that in order to have an elastic and even mass, it is an advantage to extract these substances. This is done either naturally, allowing the clarification to proceed by simple deposit, or by a direct treatment by means of filtration or a chemical. This last means, which generally consists of treating the oil with sulphuric acid, frees it from substances which do not play any part in its drying qualities, as they do not fix oxygen. As a matter of fact, in a comparative test by exposure to the air of a recently pressed oil and the same oil treated with sulphuric acid, then freed by washing from all trace of the acid, it is seen that in the second case the oil absorbs a greater quantity of oxygen. Moreover, it is evident that the final product will be the whiter, as the oil, to begin with, is less colored, which suggests the necessity of the bleaching operation.

2. Age of the Oil.—Oil preserved from the action of the air absorbs oxygen the better the older it is. It is thought that it is due to the formation of new compounds in the oil. Dr. Fahrion believes that the non-saturated fatty acids enter into combinations among themselves to form new and complex bodies.

3. Method of Preservation of the Oil.—Outside the question of age, if the oil has been kept in such conditions that it has been in contact with the air, it has already absorbed a certain quantity of oxygen. Experience shows that even if to begin with the oil only slowly absorbs oxygen, once this absorption has begun, it proceeds much more rapidly. In any given oil, therefore, the absorption of the oxygen will take place much more rapidly when it has been exposed to the air.

4. Action of Heat.—The temperature at which an oil is exposed to the air has influence upon its drying powers. Chevreul showed that linseed oil dried much more quickly at a temperature of from 25° to 28° C., than at a temperature of from 15° to 18° C. Moreover, if crude linseed oil and the same oil which has first been submitted to the action of the heat are exposed to the air under the same conditions of temperature, a difference in their drying powers will be found. If, for instance, linseed oil is heated for three hours, so that it only disengages a few gaseous bubbles from time to time, the oil becomes much more siccative, as Chevreul has shown. It takes about half as long a time to dry. Dr. Fahrion explains this by saying that, under such conditions, boiling in a deep vessel to which little of the oxygen of the air can gain access, the combination of the non-saturated fatty acids among themselves is accelerated, and complex products are formed capable of absorbing oxygen more rapidly.

Chevreul, in continuing to heat the linseed oil under the same conditions, proved, on the other hand, that the oil heated for five hours is at the end of this time less siccative than the oil heated for three hours only. It is probable that under the influence of this pro

longed heat a part of the glycerine is destroyed, as a certain acrid smell indicates, and the linoleic acid is set at liberty, and it is known that linoleic acid dries less quickly than linolein. It is probable for the same reason that Mulder has found that linseed oil heated only to from 70° to 100° C. dries less well than crude oil. We can sum up, therefore, as follows: First, that a moderate temperature assists the drying of the crude oil; secondly, that exposed to the same temperature the crude oil dries less quickly than if it had first been submitted to the action of heat, with this reserve, that the action of heat has been such that the oil has not commenced to decompose, with the result that a certain quantity of linoleic acid has been set at liberty.

5. The Addition of Certain Substances.—Long experience has shown that the addition of certain substances, such as white lead, litharge, oxide of manganese, etc., assists the drying of a siccative oil. In certain cases these substances are mixed directly with a cold oil, in other cases heat is used in making the mixture.

Let us first consider the plumbic compounds which have been employed for a long time as driers. The commonest process consists in heating the oil with these plumbic compounds, and the increase of drying power has been attributed sometimes to the formation of linoleate of lead, at the same time that linoleic acid is liberated by the heat, and sometimes to the oxidation produced by the oxygen of the oxide of lead, pointing out as a proof of this that at the end of the operation there is a deposit of a certain quantity of metallic lead.

This double explanation does not seem exact, for the following reasons: In the first place, experience teaches that linoleate of lead gives only factitious drying power, since the product quickly becomes brittle and friable. On the other hand, linoleic acid dries less quickly than linoxine. Nevertheless, it is indisputable that an oil heated with oxide of lead has a drying power greater than a crude oil, or oil cooked without the addition of the oxide. It may be asked, therefore, if it is not owing to the oxygen of the oxide of lead that the drying power is augmented. If it is remembered that a linseed oil of good quality, exposed to the air, absorbs 16 to 18 per cent. of its weight on turning into a solid and perfectly dry substance, and if, on the other hand, we reflect that in practice the quantity of oxide of lead used is not more than 3 to 8 per cent. of the oil, it will be seen that the oxygen that the oxide of lead could furnish is less than 1 per cent. of the weight of the oil, whereas from 16 to 18 per cent. are necessary, and that, therefore, it cannot play anything more than a secondary part from the point of view of direct oxidation, the more so that a part of this oxide of lead does not give up any of its oxygen, since it enters directly into combination to form a plumbic soap. Nevertheless, the presence of a certain quantity of metallic lead at the end of the operation proves that a corresponding quantity of oxygen has been at liberty to commence the oxidation of the oil, and, as we have seen in studying the effect of oxygen on crude oil, the drying proceeds more rapidly after the oxidation of the oil has reached a certain degree. In any case, this reaction seems to be a secondary one, in view of the notable increase of the drying power. The same objections and the same explanation might be made on the subject of the augmentation of the drying power by the use of manganic compounds.

However, a more acceptable explanation may be given, based upon a very important observation made by Chevreul, who showed that if linseed oil were spread on a sheet of lead entirely freed from all trace of oxide, the drying power of the oil notably increased. It is evident in this case that the oil cannot absorb any oxygen, except that which is furnished normally by the air. The augmentation of the drying power is due really to nothing else than the presence of the metal. This experiment may be carried further. If a crude siccative oil is shaken up in a bottle, with very porous lead, obtained by the precipitation of a salt of lead by another metal, it will be seen that without the necessity of any elevation of temperature the siccative oil has a much greater drying power than before this treatment, and in this case it is certain that the oil has not been furnished with any oxygen. The only certain modification is that after the treatment with precipitated lead the oil contains a small quantity of the metal, and we are led to conclude that the augmentation of the drying power is due uniquely to the presence of this small quantity of lead.

The same experiment cannot be made directly with the manganic compounds, but indirectly the oil can be placed in the same conditions with regard to manganese. To do this it is merely necessary to stir up the oil treated with the precipitated lead with a salt of manganese, the sulphate, for instance, which by double decomposition gives a salt of lead insoluble in oil and at the same time manganese as a substitute for the lead. Following out this experiment, it is shown that the oil thus "manganesated" has a very great drying power, superior even to that obtained by heating crude oil with a manganic compound. It is by experimenting upon this manganesated oil thus prepared that it is possible to find an explanation of the augmentation of the drying power. If this oil is spread in a thin coat in contact with the air, it is seen to take a brown tint, due to the oxide of manganese present passing to a superior degree of oxidation, by taking oxygen from the air. But as the oil becomes more viscous the brown tint is seen to disappear; finally this coloration disappears completely, the oxygen of the peroxide of manganese having served to oxidize the siccative oil, and finally a solid mass without color is obtained.

This brown coloration, followed by a complete loss of color, shows that the oxide of manganese has served as an intermediary, itself oxidizing easily by contact with the oxygen of the air, and then giving up this oxygen to the oil.

The action obtained with oxide of lead is very probably similar to this, but with a smaller degree of energy. In an oil to which litharge or manganese has been added, the lead and the manganese play a part of intermediaries, robbing the air of its oxygen to give it up in a continuous manner to the oil, which is thus oxidized more rapidly than it would be without these intermediaries.

It was natural to try if other metals were capable of playing the same part as lead and manganese. The simplest way of experimenting in this direction is to take an oil to which litharge has been added and stir it up with salts of the different metals, to find out which will give with the lead a salt insoluble in the oil. Operating thus, we have proved that if the oil prepared with litharge spread in a thin coat on a plate of glass dries in twenty-four hours, the oil in which the lead is substituted by manganese dries in six hours; by substituting copper, zinc, or cobalt for the lead, the oil takes from thirty to thirty-six hours to dry; and, finally, the oils obtained by substituting nickel, iron, chrome, etc., for the lead are not completely dry until forty-eight hours have elapsed. A very important point to note is that a manganesated oil got by substituting manganese for the lead of an oil prepared with litharge dries much more quickly than an oil manganesated directly.

In practice, in addition to the oxides of lead and of manganese, certain salts of these oxides are used, but their choice seems as if it should be subordinated to their degree of solubility in the oil and the manner in which they behave when heat is employed. In practice, moreover, of all the salts proposed, none other than the acetate of lead and the borate of manganese have been retained, and the explanation of this is easy. It is that these two salts submitted to the heat decompose and give finally either the oxide of lead and very finely divided lead or the oxide of manganese. To take the case of the acetate of lead, it is known that this salt melts in its water of crystallization at about 75° C.; at a temperature higher than 100° C. it loses water and a little acid, giving a sesqui basic acetate, which is completely decomposed at about 290° C. Carbonic acid and acetone are freed, and as a residue very finely divided lead is obtained, of which we have already seen the important role as a drier.

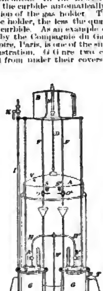
In the case of borate of manganese we have to deal with a very unstable salt, as most of the borates are. The affinity of the boric acid for the oxide of manganese being very weak, under the influence of heat the latter is set at liberty. The use of this salt is, therefore, simply an advantageous way of introducing the oxide of manganese.

As experience has shown that metallic lead in a very porous state augments the drying power of the oil, it was interesting to study the action on the oil of other metals easy to obtain by precipitation. In operating, however, with precipitated copper and tin, it was found that the drying power of the oil did not sensibly increase. This result was to be foreseen, for Chevreul had shown that linseed oil spread on a well cleaned sheet of lead dried much more rapidly than that spread on sheets of copper, brass, zinc or iron. With these metals the drying power was not much more rapid than if the oil had been spread on porcelain, glass, or plaster.—Vernis et Huiles Siccatives; from the Western Painter.

RECENT IMPROVEMENTS IN ACETYLENE GAS GENERATING APPARATUS.

The means for producing acetylene gas are constantly being improved in Paris. Low pressures alone are favorably considered. A very important industrial exhibition just closed in that city showed that inventors are not idle in devising apparatus for giving better results.

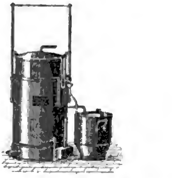
The superproduction of gas after the cessation of consumption has met with the most attention in recent appliances. This inconvenience was combated in Trouvé's generators some eighteen months since by glass rings dividing the carbide into parcels, and so, in some measure, preventing a too rapid attack upon the whole of the chemical. In the newest machines the water is fed to the carbide automatically by the movements of deflation of the gas holder. The higher the elevation of the holder, the less the quantity of water allowed to the carbide. As an example of this type of machine, that by the Compagnie du Gaz Nouveau, 64 Rue de la Victoire, Paris, is one of the simplest for the purpose of illustration. G G are two cast iron pots, readily slid out from under their covers for the pur-



pose of refilling. H H¹ H² connect the generators to the gas holder, A, to the top of which is attached a chain, D, acting upon a stop plug, N, within the water reservoir, B, so that the water therein is opened to or cut off from the two supply pipes, F F, feeding the carbide holders. The supply is commenced automatically by means of two spring catches, S S, attached to the sides of the gas holder, pressing back the lever cocks, O O¹. A little water poured in at one of the funnels starts the holder. K is the gas supply pipe from the gasometer. V is a safety valve, as a precaution against any hitch with the holder; and as the generator pots are closed by the cocks, R R¹, when the apparatus is not in use there would be a chance of these cocks being left shut through a forget when they should be open, so each pot is fitted with a water siphon, the seals of which would naturally be broken by any excess of gas in the generators.

Only one generator is used at a time under ordinary circumstances, and as soon as the charge in one is exhausted the other is started, so that the gas supply can be kept up indefinitely.

The smallest apparatus made contains about one pound of calcium carbide in each generator, or one kilogramme in all. This charge is good for ten hours



with three burners going, each burner using ten liters per hour. The price of the machine complete (and which is well made) is 140 francs. The size of the gas holder is 19½ by 19½.

Another apparatus, by V. Daix, 72 Rue Louis Blanc, Paris, has the same system for feed water supply, but, instead of using taps in his connecting pipes, this inventor uses water siphons throughout as being less liable to cause errors of working; and, still more important, he divides the carbide into a number of small lots, each of which is preserved from the action of water or vapor until the supply calls for its use. Superproduction of gas is thus reduced to a minimum, as will be readily understood. The inventor estimates that as much as thirty-five per cent. is lost by superproduction in apparatus in which the carbide is not subdivided and preserved from the action of vapor.—Photography.

FOOD TABLETS.

Not long ago an American chemist, evidently a disciple of Prof. Berthelot, of France, stated that the time was near at hand when hot water and food tablets would be the sole accouterments of a kitchen; that the essential food elements of a twelve hundred pound steer can be put into an ordinary pill box, and that a single concentrated soup tablet the size of a pea will make a large bowl of soup of full nourishing strength. A ration case weighing eight ounces was planned. It contained the following supply: Three tablets of concentrated soups, equal to three quarts; four beef tablets, equal to six pounds of the meat; one milk tablet, equal to one pint; two tablets wheaten grits, equal to two pounds; one tablet egg food, equal to twelve eggs.

Viewed from a chemical standpoint, it may seem possible to reduce, by condensation, the bulk of man's food almost indefinitely, and thus furnish in a thoroughly portable and convenient form nutriment for the body which will remain unchanged through long periods of time and in spite of the influence of varying conditions of temperature and climate; but from a physiological point of view may be seen serious obstacles to the successful consummation of such a proposition. That condensed and concentrated foods have a direct sphere of usefulness will not be denied, but that food tablets and similar products are well adapted to constitute the sole food of healthy men for any length of time is an undeniable fallacy. Combined with fresh foods they may yet prove of service; for, like the particles of yeast added to the dough, the necessary principle contained in the ordinary food may leaven the whole lump.

But practical experimental evidence is always most convincing and hence we append the following dispatch which recently appeared in a reliable periodical: "A dispatch from Denver was published stating that the troops at Fort Logan have made the first test of the new emergency ration. One company went out for three days of forced marching in the foothills of Denver, loaded with coffee tablets and compressed soup that was supposed to contain all the advantages of hard tack and coffee. On the night of September 11, the medical officer charged with weighing and watching the men rode into Morrison for assistance. He reported that thirty-six out of the fifty men are down with griping pains resulting from the non-assimilation of the scientific ration. The order could not be revoked, and the men in the field were informed that they would have to remain on the march for two days longer."—Dietetic and Hygienic Gazette.

A TRAVELING NURSERY

And now comes the traveling nursery to take its place alongside the barber shop, bathroom, etc., on our fast trains, says the Railway Review. The traveling nursery is to take up about the same amount of space as the private stateroom of the ordinary sleeping car. There will be a saving of a space of several feet, however, as the wide seats on the sides of the stateroom below the berths are not needed in the nursery, being replaced by ottomans and tiny easy chairs scattered over the floor. In this way any danger from sudden starts or sharp curves is obviated. As a further protection against injury to the little ones, the walls of the nursery are heavily padded and the floor thickly carpeted, so that bumps and bruises will be altogether avoided. At each end of the compartment, and firmly secured, are two cozy cots in which the smaller children may lie and watch the games of the older ones. Each car containing the nursery attachment will carry a matron or nurse, who will be selected with special re-

ference to her ability to amuse and care for her little charges; and she will have at hand supplies of milk, cookies and other edibles and drinkables dear to the infantile heart. She will also have charge of a medicine chest containing a full assortment of the simpler remedies for childish ailments. A miniature toy shop is another adjunct of the traveling nursery, and it will contain everything from baby rattles to picture books and fairy tales. Nothing, in short, will be missing that would add to the comfort or amusement of the young travelers. It is not intended that every sleeping or parlor car can be provided with the nursery attachment. Large as is the number of children passing, it would be necessary to have but one such car in every through train running between the larger cities. The expense of equipment, matron's wages, etc., would thus be kept down to a reasonable limit. Although child travelers are numerous now, and the sending of them alone from one city to another is increasing each year, railroad officials who have examined plans for the new compartment anticipate an increase in business through their adoption. It will not be long before the railroads will be able to advertise "all the comforts of a home," while en route.

NITROSYLIZED BLAST FURNACE SLAG AS AN ADDITION TO HYDRAULIC CEMENT.

WHEN a cement briquette is kept immersed in water for several months, it loses considerable of its lime, say from 5 to 10 per cent. This portion of the lime is in excess of combination, the cement composition being too basic to yield to it sufficient gelatinous silica to bind it. Hence, nearly all hydraulic cements can be improved by the judicious admixture of siliceous substances, that yield an additional supply of gelatinous silica. The volcanic earths, such as trass, santorin and puzzuolane, possess this property to a remarkable degree, but they are not much used for admixture on account of their comparatively high cost. A much cheaper and in some respects excellent substitute is found in blast furnace slag of singulo to sesqui-silicate constitution, high in alumina and lime, and finely pulverized. Dissolving lime reacts only superficially on such admixtures, but it extracts from them a little gelatinous silica, and the resulting compounds—minute particles of hydrosilicate—cement the mass more firmly.

Unfortunately, such slag contains from 1 per cent. to 3 per cent. of calcium sulphide, which is easily decomposed by water containing carbon dioxide. This sulphide obtains in the slag in intermolecular combination, which means that it is rather evenly distributed throughout the whole mass, and that even the smallest slag particles contain some of it. In dissolving—under the conditions in which it obtains in applied cement—it changes readily to calcium-sulphhydrate; the latter, being in aqueous solution, becomes mixed up with the gelatinous silica and with the dissolved lime, and the lime changes it back to sulphide. Thus the forming particles of hydrosilicate, which are to bind the mass more firmly, become tainted with unstable sulphur compounds, hence they are apt to disintegrate and to cause the cemented mass that contains them to weaken long after it has become indurated, sometimes after the lapse of years.

In order to illustrate the slag question more fully, it may be as well to sum up as follows: Crude slag that is sulphurous cements well at first, but is not a reliable constituent, and crude slag that is not sulphurous is usually so acid as to exert scarcely more chemical energy than ordinary sand does. There is, practically, no intermedium, for even the singulo-silicate slag from charcoal blast furnaces contains sufficient of CaS to be, in its crude state, objectionable for the purpose herein considered.

In order to free blast furnace slag from this objectionable feature, several methods have been proposed for desulphurizing such slag in its molten state; but they have not yet been tried, the chief obstacle being that blast furnace managers are very reluctant to try anything that is apt to interfere in the least with other routine work. Moreover, with Rosendale cement selling as low as 70 cents for a barrel of 300 pounds, and with Portland selling as low as $2 for a barrel of 380 pounds net, the cement producers are not over-anxious to adopt any new ingredient unless its use will cheapen the cost of their product considerably; and so the matter rests.

There is, however, a possibility that the recently invented process of nitrosylizing pulverized slag will prove to be of greater commercial interest to both classes of these industries than anything that has thus far been attempted with that much neglected by-product. The main reason for this assumption is, on the one hand, that the condition in which the slag is to be delivered from the dump and paid for can be brought about by the furnace men without causing them any appreciable inconvenience, and on the other, that the slag which is thus delivered can be adapted for cement at a smaller cost than that which would be involved by any other effective treatment that has thus far been proposed. The treatment itself is very simple and offers no new features of general interest; it is fully described in the patent specifications (United States patent, No. 579,890, March 30, 1897), which are rather too long to be reproduced in this paper. Suffice it to state that nitrosylized slag is prepared by moistening finely ground slag of suitable composition with a weak solution of nitric acid, by adding more water after the acid has become neutralized and by drying the leached mass. The complete treatment requires about one-half a pound of 60 per cent. acid (N_2O_5) and about 30 pounds of water for each 100 pounds of pulverized slag, and the product is cheap enough to be even sought after by the manufacturers of Rosendale cement.

The primary object of the treatment is, of course, to eradicate, as it were, the CaS that crops out on the surface of the slag particles. The total quantity that becomes thus eliminated is rather small, and when the acid is used in the above-mentioned proportion it amounts to less than 0·1 per cent. with slag that contains about 2 per cent. This superficial desulphurization is, nevertheless, very effective, for the pores that are produced by the elimination of the sulphide are apt to become closed up by the formation of hydrosilicates in the beginning of the cement reactions, and before any deeper reaction can set in, and thus any future deleterious action of the remaining sulphide is rendered impossible.

The secondary, but not less important, object of the treatment is to utilize the nitrosyl that is set free by the nitric acid while it reacts on the slag particles. In other words, slag of singulo to sesqui-silicate constitution, and high in alumina, contains constitutionally—or aside from purely accidental ferruginous matter—more or less of ferrous silicate, say from 1 to 3 per cent. It is well known that attenuated solutions of ferrous salts absorb nitrosyl with great avidity and under evolution of heat, the thermal effect ranging, according to various authorities, from + 9° to + 11° calories. The ferrous silicate of the slag absorbs it likewise; hence it is to be presumed that this absorption must render its silica more disposed to sever its connection with the ferrous oxide, and to become gelatinous, when reacted upon by dissolving lime. The accidental ferruginous matter of the slag also absorbs nitrosyl and is thereby prevented from readily changing on its surface to ferric hydrate. As the formation of ferric hydrate involves an appreciable enlargement of the volume of the particles thus affected, it stands to reason that such a change is not desirable in applied cement; and as one volume of nitrosyl gas requires twenty volumes of water for its solution, it is not likely that nitrosylized slag is apt to "rust" very quickly.

Coming now to the question of the actual efficiency of nitrosylized slag, the writer has arrived at the following conclusions:

1. High-class Portland cements, those that have been ground from carefully prepared stock that has been burned very hard, can only be improved by the admixture of small quantities, probably not exceeding 10 per cent. in the average.

2. Inferior Portland cements may be mixed with about their own weight of nitrosylized slag, and still give as good results as the neat. The following tests, recently made in the usual way, with briquettes of standard size, may serve as an illustration:

A.—TEST OF HIGH-CLASS PORTLAND CEMENT.

No.	Composition of Mixture.	Water added. Per cent.	Age. Days.	Tensile strength per square inch. Pounds.
1	Neat cement...........	[illegible]	19	[illegible]
2	" "	[illegible]	17	[illegible]
3	Cement: 90%, slag: 10%.....	[illegible]	18	[illegible]
4	" 60%; " 40%.....	[illegible]	19	[illegible]

B.—TESTS OF AN INFERIOR PORTLAND CEMENT.

No.	Composition of Mixture.	Water Per cent.	Age. Days.	Tensile strength Pounds.
1	Neat cement...........	22	18	310
2	Cement: [illegible]; slag: [illegible]......	17	19	[illegible]
3	" [illegible]; " [illegible]......	16	19	[illegible]

Briquettes made up of cement, nitrosylized slag and sand are apt to give rather poor comparative results as regards their test for tensile strength unless the sand is added after the cement and the slag have been thoroughly wet-mixed, for it is scarcely possible to dry-mix three different substances as well as two. A much fairer test would be to slurry the mixtures, just as is done in working cement for the "second set," and to fill the slurry into the moulds without beating it. The limit of tensile strength would then be barely as high as in testing by the usual method, but it would certainly be more in accord with the amount of resistance which the respective mixtures actually acquire in being applied to masonry.

A briquette, made by casting the mixture into the mould, and composed of

Cement "A" 90 per cent. and nitrosylized slag 10 per cent., the water added being 30 per cent., broke when 17 days old at 350 pounds tensile strain per square inch. This is a pretty fair result, considering that this mode of testing is apt to lower the limit of tensile strength of even the best cements 40 per cent. or thereabout.

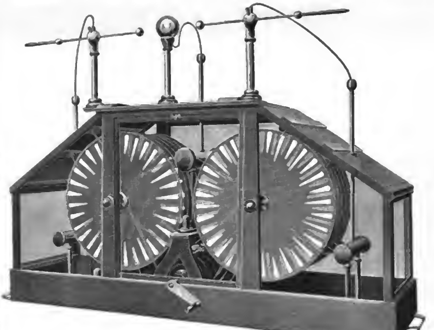
The above notes were published by Mr. A. D. Elbers in the Engineering and Mining Journal.

SOIREE OF THE ROYAL SOCIETY.

THE last Royal Society soiree took place at Burlington House in May. The place of honor in the council room was given to Mr. A. A. C. Swinton, whose researches into the nature and behavior of X rays are so well known.

Mr. Swinton's experiments dealt both with cathode rays and X rays. In relation to the former he showed that by replacing the usual screen of fluorescent material by one of ordinary electric light carbon, much appears which was previously invisible. When a concentrated stream of powerful cathode rays is focused on a surface of carbon, a brilliant luminescent spot appears on the carbon at the point of impact of the rays. The effect is entirely on the surface, and when the cathode stream is rapidly deflected by a magnet the luminescent spot moves with no perceptible lag. The tube in which these phenomena were shown was kept connected to the pump, because the vacuum is rapidly reduced by the hydrocarbons thrown off by the carbon.

In tubes of the ordinary focus type with a single spherical concave cathode the rays appear to converge in a cone to a focus, and if the vacuum be not too high, to diverge again in another cone upon the other side of the focus. At higher vacua the rays do not appear to diverge again at once, but seem to form themselves into a thread which connects the convergent and divergent cones. Mr. Swinton showed that, if the divergent cone is thrown on to a thin platinum disk, it quickly attains a red heat. The disk usually becomes uniformly heated, but if an electric light carbon disk be employed, there is, in some cases, seen an apparently white hot ring with a well defined dark and seemingly cold interior. As the dimension of the cone of rays is varied by altering the vacuum, the ring alters correspondingly in diameter. Mr. Swinton has, also, been able to show that the converging cone of rays also acts under certain circumstances as if it were hollow. In order to investigate the cathode rays in a focus tube still further, and more especially in order to discover whether the various rays cross one another at the focus, or again diverge without crossing, Mr. Swinton showed a tube with a carbon anti-cathode which was also the anode, fixed at the opposite side of the focus from the cathode, with the focus about equally distant between it and the cathode. A section of the aluminum cathode, equal to about one-eighth of its total area, was removed. When the luminescent ring was produced, it was shown that instead of one-eighth of the circumference being wanting, actually seven-eighths were missing. The portion of ring that did appear was of a length corresponding exactly to the arc of the removed section of the cathode. Hence it appears that there is no rotation of the cathode beam as a whole, and that the rays do not cross at the focus; and further, that when the hollow convergent cone is, as it were, split in this manner, some unexplained action, similar in effect to a circular surface tension, causes the gap to widen out and the remaining portion of the ring-shaped section to contract correspondingly, without, however, altering its diameter. Another tube designed to investigate the same matter was shown. In this the cathode was of the usual form, but a small aluminum spike could be moved up and down the tube between the cathode and the anti-cathode. This piece of aluminum projected from the wall of the tube nearly to the center, and filled up very nearly one-quarter of the circular sectional area. On putting this obstacle slightly in the divergent cone, exactly one quarter of the ring



THE WIMSHURST INFLUENCE MACHINE AT THE ROYAL SOCIETY SOIREE.

on the anti-cathode failed to appear, and this result was maintained when the obstacle was moved farther into the cone. There was no displacement of the gap, and no rotation of the divergent cone. The point was then moved into the convergent cone of cathode rays, when a small portion of the ring on the carbon was cut out, but on the opposite side, showing that the rays cross one another's paths at the focus without rotation.

Mr. Swinton's experiments with X rays were directed to showing how the penetrative power could be varied to suit different conditions. It is known that as the vacuum is improved the rays become more penetrative, until a point is reached when the bones of the hand become almost as transparent as the flesh. Similarly at any degree of vacuum, the penetrative value is increased by increasing the power of the Ruhmkorff coil. Similar results can be obtained by varying the resistance of the tube by means of a magnetic field. The simplest method, however, is, as Mr. Swinton showed, by altering the distance between the cathode and anti-cathode. He had a tube in which the anti-cathode of aluminum, faced with platinum, was connected to the anode by a sliding steel rod, so that it could be moved along the axis of the tube, and the distance between the cathode and the center of the anti-cathode varied from 1 in. to 3 in., the anti-cathode being always outside the focus of the cathode. As the anti-cathode was moved toward the cathode, the penetrative value of the rays, as seen on a screen, was visibly increased, and when the motion was in the opposite direction, there was a corresponding decrease. Another tube had two cathodes, both focusing on opposite sides of the same platinum anti-cathode. The two cathodes were of different diameters, one being 0·375 in. and the other 1·125 in. With a degree of exhaustion that gave plentiful X rays with the small cathode in action, no X rays could be obtained by aid of the larger cathode. When the exhaustion was carried further, X rays of low penetrative power were produced from the large cathode, and rays of greatly increased penetrative power were obtained from the small cathode. In another lamp there were four anti-cathodes of different sizes, any one of which could be turned to face the cathode, and it was shown that the smaller the anti-cathode, the greater was the penetrative value of the rays. The penetrative value of the X rays produced by any given tube appears, therefore, to be dependent upon several conditions:

1. The penetrative value is higher for a high vacuum than for a low vacuum.

2. It is higher when the electrical power applied is great than when it is small.

3. It is higher when the resistance of the tube is great than when this resistance is reduced by magnetic means.

4. It is higher when the distance between the cathode and anti-cathode is small than when the distance is great.

5. It is higher when the cathode itself is small than when it is large.

6. It is higher when, as a consequence of one or more of the above, the potential difference between the cathode and the anode portion of the tube, and consequently the electrical excitation of the cathode, is great than when it is small.

Mr. Swinton's experiments attracted a large gathering all the evening, and excited the liveliest interest.

Another electrical exhibit of a curious and interesting nature was that of Mr. J. W. Swan. He showed a number of glass dishes containing resin covered with patterns of great complexity and much beauty. These were produced by placing the resin between two poles of an induction coil in action. No spark passes to the resin, which is merely subjected to strain, the spark being taken between an auxiliary pair of terminals. When the resin is removed it shows no trace of any effect. If, however, it be warmed through, the surface puckers up into patterns as the mass softens, owing to internal strains set up by the electric stress, which do not seem able to relieve themselves while the resin remains hard. These strains persist for a long time—for weeks, if not months.

Some of the samples shown had been developed three months after the resin was electrified. The patterns produced at the negative pole were quite different from those at the positive pole. Before the heating the plates were exposed to dust. In one dish there was a viscous mixture of resin and oil which flowed under electrification, and heaped itself up in various patterns.

Mr. James Wimshurst has lately constructed the machine which we illustrate. This, as will be seen, is of immense size—much larger than has ever been seen in London before—and gives torrents of electricity. Like everything shown by Mr. Wimshurst, it has been entirely designed by himself, and made in his own workshop, largely by his own hands. It is duplex in form, and on each side contains 12 plates, 30 in. in diameter; on each plate there are 32 sectors, the arrangement being such that the machine excites itself with absolute certainty before the handle has made a complete revolution. The length of spark is 32 in. between the two outer terminals, the large ball in the center forming a sort of half-way house between the two outer ones. The outside dimensions of the machine are 9 ft. in length by 2 ft. 9 in. in width.—Engineering.

EXPORTS TO LATIN AMERICA.

THE good ship Mexican Prince, which sailed from New York recently, had on board a somewhat diversified cargo, the details of which may do as a very fair illustration, says the New York Sun, of the variety of the cargoes sent from this city to South American ports. The notion is general that New York's chief exports to Europe are cereals, provisions, petroleum, and tobacco, and to South American ports machinery. But a mixed cargo to South American ports is a mixed cargo, indeed, if the case of the Mexican Prince may be taken as a sample.

There were 3 cases of refrigerators, 20 of bicycles, 11 cases of typewriters' supplies, 21 packages of empty bottles, 13 cases of baking powder, 20 cases of scales, 75 consignments of plows, 5 cases of tooth powder, 20 consignments of oars, 1 case of bird cages, 1 of slot machines, 81 consignments of pumps, 1 case of photographs, 27 consignments of hay presses, 12,000 boxes of matches, 2 bales of seed, 2 consignments of rakes, 4 consignments of emery wheels, 2 cases of cigarettes, 8 consignments of desks, 4 consignments of bedsteads, 4 consignments of cartridges, 80 boxes of clocks, 2 cases of towel racks, 31 harvesters, 1 case of phonographs, 24 boxes of soap, 40 stationary engines, 152 sewing machines, 60 cases of shoe blacking, 108 consignments of chairs, 11 cases of typewriters, 400 paper boxes, 3 consignments of firearms, 6 consignments of toys, 165 boxes of carpet tacks, 800 sets of harness, a bale of sponges, 39 cases of sandpaper, 377 packages of illuminating lamps, 5,000 pounds of candy, 15 machines for rice manufacture, 26 bales of wicks, 700 gallons of benzine, 100 pounds of confectionery, 1,000 gallons of naphtha, 1,000 yards of oilcloth, 377 consignments of cutlery and 200 bottles of American medical bitters.

On the same day the good ship Finance cleared for Central America with a mixed cargo of candles, hardware, photograph apparatus, stationery, paper, and drugs. Other items of American exports to South and Central America were cotton duck, sausages, pumps, codfish, hats, lamps, telephone receivers, perfumery, carts, bottled beer, clothes wringers, paints, staves, stove polish, bellows, whips, oleomargarine, cartridges, peanuts, tape, cider in barrels, coffee roasters, ice cream freezers, crucibles, twine, hoes, forks, oats, needles, wheaten grits, and netting. American exports to South and Central American cities are much more varied in kind than is usually believed to be the case. The exportation of agricultural implements is large to only one country of South or Central America—the Argentine Republic. American books are extensively exported to Brazil, coal to Cuba, machinery to Brazil, lard to nearly all South American ports, dairy products to the West Indies, wool to Honduras, wooden manufactures to Mexico, fish to the West Indies, cotton goods and wearing apparel of cheaper variety to the Central American states.

SOME SHIPS OF THE ANCIENTS.*

NOAH'S ARK.—The first vessel ever known to have floated on the face of the deep, as well as the largest, may well claim to have a first place among the most remarkable ships. Burchett, in his "Naval History," alluding to the ark, says, "To the immediate providence of God are we to attribute the invention of shipping." Beyond its dimensions and the object of its construction, we have but little record of this primitive vessel. The following is the description of the ark as given in the sixth chapter of Genesis: "And God said unto Noah, make thee an ark of gopher wood; rooms shalt thou make in the ark, and shalt pitch it within and without with pitch. And this is the fashion which thou shalt make it of: The length of the ark shall be three hundred cubits, the breadth of it fifty cubits, and the height of it thirty cubits. A window shalt thou make to the ark, and in a cubit shalt thou finish it above; and the door of the ark shalt thou set in the side thereof; with lower, second and third stories shalt thou make it." As Noah and his sons went into the ark in the "600th year of his life, in the 2d month, on the 17th day of the month," and left it in the "601st year, 2d month, 27th day of the month of his life," he must have inhabited the ark for a year and ten days. Allowing the usual measure of the cubit, which was one foot nine inches and eight hundred and eighty-eight thousandths, we find the ark was five hundred and forty-seven feet and a fraction in length, about ninety-one and a half feet beam, and was nearly fifty-five feet in height. Its tonnage has been variously estimated from twelve thousand tons to as high as forty-two thousand four hundred and thirteen tons. Dr. Hales, a writer in the Nautical Magazine, January, 1834, calculates its tonnage as eleven thousand nine hundred and five tons, and its external bulk one million five hundred and eighty thousand feet, which is nearly six thousand tons less than the capacity of that modern ark, the Great Eastern. The name would imply that it was coffer-shaped, or simply a square box, hence the calculation of its greatest tonnage, which would give it the capacity of eighteen line-of-battle ships, or about fourteen times the tonnage of one of the Collins steamships.

The ark was as long as St. Paul's Cathedral, London, nearly as broad and half as high. According to the biblical account, it was pitched within and without.

In length the ark was not remarkable, for it is exceeded by that of the Great Eastern and City of Rome, and several of our modern steamships are nearly five hundred feet long.

It would appear from the account in Genesis that it was one hundred and twenty years in building.† The wood of which the ark was constructed was "gopher wood," which has been translated cedar, pine, box, etc., but is generally supposed to have been cypress, that wood being least subject to decay, the sap of it being so offensive that no worm or other corroding animal will touch it.

The structure of the ark was adapted to the burden it was to carry and the weather it was to endure. We read that it had one door in the side, and that it had one window twenty-two inches square, which was rather a small allowance for light and ventilation, and that it had three stories, or, in other words, was a three-decker. Such is our limited knowledge of the first, and until our own times the greatest, ship the world has ever known.

Early in the seventeenth century Peter Jansen, a Dutch merchant, caused a ship to be built answering in its respective proportions to those of the ark. At first Jansen's ark was looked upon as a fanatical vision of his, and while it was building he and his ship were the sport of seamen; but afterward, says an old writer, "it was discovered that ships built in this manner were, in time of peace, beyond others, most commodious for commerce, because they would hold a third part more without requiring any addition of hands."

In length the ark was six times its breadth, which is about the proportion of the length and breadth of the large sea and war steamers of twenty years ago and of our modern clipper ships.

Whether the ark was of sufficient capacity to accommodate all the men and living things ordered into it, with the requisite provisions for twelve months, I shall not undertake to decide. It has been calculated that eight persons and two hundred and eighty pairs of quadrupeds (which, according to Buffon, is the utmost number of distinct species), with fowls, reptiles and insects that could not live under water, and all the necessary food for a year, could be easily admitted. Noah was instructed to make rooms, but, says the writer just quoted, "God's power was present, so that the harmony of the animals can be easily accounted for."

Not many years after the flood it became necessary for the descendants of Noah to construct vessels to convey themselves and their families to the territories allotted them.

The Isles of the Gentiles (Genesis x. 2–5) were assigned to the sons of Japheth, and Kittim, his grandson, according to Josephus, settled in the island of Cyprus, and from his name not only islands in general, but most maritime places, were in the Hebrew language termed "Kittim." The Isles of the Gentiles are supposed to have been the islands of the Mediterranean and Ægean Seas.

For the purpose of comparison we will state that the British steamship Inca was just half the length of the ark, and her other proportions the same, that is, her breadth was one-sixth the length and her depth one-tenth the length.

The largest vessel of war in the world in 1881 was the Italian ironclad Italia, which was four hundred feet long, had seventy-three feet beam and measured thirteen thousand eight hundred and ninety-eight tons. Her sister ship, the Lepanto, had the same length, three inches more beam, and measured thirteen thousand five hundred and fifty tons.

The largest merchant steamer and vessel in the world, in 1881, was the Great Eastern, which measured eighteen thousand nine hundred and fifteen tons and was six hundred and ninety-nine feet six inches long and eighty-two feet six inches broad.

The longest vessel in the world, in 1881, and the largest merchant steamer, save the Great Eastern, was the steamship City of Rome, whose dimensions were: Length, five hundred and eighty-six feet; breadth, fifty-two feet three inches; depth of hold, thirty-seven feet; tonnage, eight thousand eight hundred and twenty-six tons. Her weight was eight thousand tons, and her displacement at twenty-six feet mean draught was thirteen thousand five hundred tons.

Mr. James Napier devotes one section of his "Manufacturing Arts in Ancient Times" to a consideration of the particulars given in connection with the ark of Noah. According to the length of the "cubit" (either 18, 21 or 25·025 inches), the length of the vessel was from four hundred and fifty to six hundred and twenty-five feet, the breadth from seventy-five to one hundred and four, the depth from forty-five to sixty-two. The result given by calculations founded on the longest unit indicates a vessel fifty-five feet shorter than the Great Eastern, her length being six hundred and eighty feet; the lowest dimensions equal those of any vessel which we build at present for long sea voyages. He holds the opinion that the directions given in the sacred record were given in an age in which the art of shipbuilding had received considerable development. The proportion indicated—length six times the breadth—is that at present in favor in the construction of vessels designed to carry large cargoes with the greatest speed and to be capable of encountering heavy seas. "Looking at the whole structure from a workman's point of view," Mr. Napier remarks, "there would be required not less than twenty-five thousand loads of timber for its construction. The cutting down of such a number of trees as would be required, their conveyance to the building yard, the preparation of the wood for the timbers, of whatever shape they were, and the fitting of the different parts, indicate a great amount of skill on the part of the workmen. Whether the fastenings were of wood or metal we, of course, cannot decide; but, considering what we have seen of the knowledge of metals in ancient times, it is more than likely both were used." He concludes that the vessel was built upon some inland plane, contiguous to a plentiful supply of wood, an arrangement which would facilitate the collection of the cargo to be saved in the ark and account for the door in the side, as also for much of the derision of those who heeded not the preacher's warning. Mr. Napier challenges the popular notion that the waters rose gradually and steadily, the words translated "the waters prevailed" indicating that they bore down everything before them. Mr. Steinmetz, in his book on "Meteorology," concludes—from the statement that the water rose, in forty days and nights, to the height of fifteen cubits above the highest mountains—that the rate of rising was five inches per minute, or twenty-five feet per hour—sufficient to destroy every living thing in the space of half an hour. But, supposing the rate reduced to less than half, two inches per minute, no opportunity would even then have been afforded for hill climbing, as such a shower would have swept down everything movable before it. Ordinary seagoing vessels would not have furnished means of escape. "Even within our own day, in South America, earthquakes near the sea have been destructive to everything near them, and all vessels within the influence of the great wave have been destroyed, and these were but slight compared with the flood." The fact must also be considered that those who escaped would not have been likely, except in expectation of such a catastrophe, to have been provisioned for twelve months. The ark had probably then to encounter wind, waves and currents, and as a vessel without rudder in currents and wind always drifts side on, to the serious discomfort and jeopardy of every living creature on board, Mr. Napier infers that the vessel was provided with steering gear and means of propulsion. The phrase "God shut him in" does not preclude the idea that "Noah might have wrought his vessel as any captain would his ship," and "there being no apparent destination, the guidance would only be to keep it in the most favorable position for the comfort of the inmates." To the objection, "How could Noah and his three sons and their wives—eight persons in all—manage such a vessel by the ordinary means?" Mr. Napier replies, "The simplest explanation of the difficulty is that Noah and his sons,

---

* By George Henry Preble, Rear Admiral U. S. N., in the United Service.

† From this and that the age of Noah is given as six hundred years it would seem that the word that has been translated as year must mean some other measure of time than the modern year. Perhaps a lunar month was meant, which would make the ark ten years under construction, and Noah's age about fifty when he entered the ark. A wooden vessel one hundred and twenty years in building would be rather rotten when finished.

like Abraham and the other patriarchs, are named as representing their households, and these included a great many servants, both male and female. Indeed, the invitation into the ark ['Thou and all thy house'] suggests this. There are many instances of this use of language in the Old Testament history where only the head of the house is named singly, but historically he represents his whole family and adherents. The Chaldean tablet states that there were many people along with the person named—the Noah of the Bible; and as we have shown that this is not only not contrary to the Scripture account, but essential to it, we accept it as strong evidence of the correctness of our opinion." To the objection that might be urged that this explanation minimizes the amount of miraculous intervention ordinarily associated with the preservation of the ark and its inmates, Mr. Napier replies that "a continued miracle is contrary to God's way of dealing when the effect can be obtained under the ordinary laws."

The Leontophorus, mentioned in Memnon, and related as translated by Palmerius, was a ship admirable as well for its beauty as its bulk; it had eight tiers of oars, one hundred in each tier—eight hundred on each side, and in all sixteen hundred: This passage and some others have occasioned a great controversy among antiquarians, whether there were more than one man at the long oars of ancient ships, it seeming a thing impossible for such long oars to be managed by one man.

Demetrius Poliorcetes seems to have been the best shipbuilder among the ancients. Plutarch reports that the bulk of his ships surprised his friends, and their beauty created some delight in his enemies. He built two ships of sixteen and another of fifteen ranks (banks?) of oars, which moved as easily as those of lesser size; and warlike machines for sieges so well contrived that they astonished his enemies; so that Lysimachus, his mortal foe, having obtained the power of seeing his ships and machines, surprised at the contrivance, cried out that they were built with more than human art.

A very extraordinary ship was built by Caligula, adorned with jewels in the poop, sails of many colors, large porticos, bagnios or baths; rooms for entertainments richly furnished, also decorated with vines and fruit trees in nice order. This ship foundered in the sight of Claudius, and was irrecoverably lost in the port of Ostia.

Athenæus* gives a list of the fleet of Ptolemy Philadelphus, viz.: Two of thirty tiers of oars, one of twenty, four of thirteen, two of twelve, fourteen of eleven, thirty of nine, thirty-seven of seven, five of six, seventeen of five, four of three and a half tiers, which were called triememiolia. The rest of the ships which were distributed about the whole empire were above four thousand.

THE ALEXANDRIA OR ALEXANDRIAN.—This celebrated vessel, built for Hiero, King of Syracuse, under the direction of Archimedes, intended for a corn trader, was at first called the Syracuse; but when Hiero presented her to Ptolemy he named her the Alexandria. She was built during or preceding the siege of Syracuse, which terminated 213 B. C., and though armed for war, had all the sumptuous fittings of a pleasure yacht, and yet was ultimately used to carry corn. Her dimensions are not given.

This ship, famous in ancient times, and a wonder even now, was the subject of a particular treatise by Moschion, the substance of which has been fortunately preserved by Athenæus, and is here presented: For the making of this ship (he tells us) there was cut down on Ætna so much timber as would have made sixty ordinary galleys; besides which the wood for treenails, ribs, and knees was procured from other parts of Sicily and from Italy, and materials for cordage were fetched from Spain and the river Rhodanus, as were other necessaries from other places. King Hiero, having hired shipwrights and other workmen for their services, placed Archias, a Corinthian architect, over them, but all under the supreme direction of Archimedes; and exhorting them to carry on the work diligently, and, to encourage them in it, he would be whole days present at their labor. The number of men employed was three hundred master workmen, besides their servants, who in six months built the ship up to the half of its designed height; and as the several parts were finished they covered them with sheet lead to preserve them from the injuries of the weather. When thus far advanced Hiero ordered her launched, that the rest of the work should be perfected afloat; but how to get this vast pile into the water they knew not, until Archimedes invented the engine called the helix, by which with a very few hands he drew the ship into the sea; when in six months more she was entirely completed and driven full of large nails of brass, many ten pounds weight and others of fifteen, which were let into the timbers by large auger holes, to rivet them well together, and covered on the outside with pitched cloths, over which were nailed plates of lead.

The ship had twenty-five banks of oars and three decks, to the lowest whereof next the hold there was a descent by several pairs of stairs. The middle deck had on each side of it fifteen apartments for dining, each furnished with four couches such as are used to recline on at their meals. On the same deck was accommodation for the mariners, having fifteen couches and three large chambers for men and their wives, each having three beds; next which was the kitchen on the poop, the floors of all which were paved with mosaic, representing the whole story of the Iliad. Suitable to so rich a floor was the workmanship of the ceilings and door to each apartment. On the upper deck was a place for exercises and a fine walk, wherein were several garden plots furnished with plants of all kinds, which were watered by leaden pipes laid to them from a great tank or reservoir of fresh water, where were also arbors of ivy and vines set in hogsheads of earth, whose roots were in the same way watered. Next to these was a department devoted to the pleasures of love, the pavement of which was of agate and other of the richest stones that were found in Sicily. The roof was of cypress wood, and the doors of ivory and the wood of the almond tree. It had three beds in it, and was richly adorned with pictures, statues, and drinking vessels of exquisite workmanship. Adjoining this was a room for retirement and conversation, which was furnished with five couches and wainscoted with box, having doors of the same wood. Within this there was a library, and in the ceiling thereof a fine clock made in imitation of the great dial of Syracuse, as also a bagnio or bath with three brass cisterns, and a bath which held forty gallons, adorned with gems called tauromenites. There were also a great number of cabins for the marine soldiers, together with twenty stables for horses, ten on each side of the deck, and good accommodations for the horsemen and grooms. In the forecastle was the tank for fresh water, made of planks well lined with cloth and pitch, which held two hundred and fifty-three hogsheads, and near it was a well lined with sheet lead, which, being kept full of sea water, nourished great numbers of fish. From the ship's sides there jutted out several beams, whereon were made places for keeping wood, as also ovens, kitchens, mills, and other necessary offices, each of which beams was supported on the outside by a carved image nine feet high.

The whole ship was handsomely painted. She had eight wooden towers, two on the forecastle, two on the poop, and the remaining four amidships; from each of these there jutted out two beams, whereon was raised a breastwork full of loopholes, from whence an enemy might be annoyed with stones. Each tower was full of those and other missive weapons, and was constantly guarded by four soldiers completely armed, with two archers. On this upper deck there was also raised a stage with a breastwork around it, whereon was placed a machine invented by Archimedes which would fling stones of three hundred pounds weight and darts eighteen feet long a distance of a hundred and twenty paces. Around this machine were hung by chains of brass curtains composed of large cables for its security. The ship was furnished with three masts, and each of them with two engines for throwing stones, from whence also large iron hooks and dolphins of lead were to be flung into an enemy's ship. It was also fortified with an iron palisade all around to prevent an enemy's boarding, and had grappling irons in readiness in all quarters wherewith to seize and bring to such hostile vessels as it might be engaged with. Sixty soldiers completely armed kept constant guard on each side of the ship, and as many at each of the masts and their respective engines. The "round tops" were of brass, and constantly guarded by three men in the main and two in each of the others, to whom, in case of action, stones were to be conveyed in baskets by the help of certain tackle for that purpose, and they were to be supplied with darts and arrows by boys appointed to that service. The fore and mizzen masts for this marine monster were without difficulty procured in Sicily, but a main mast of proper dimensions was hard to be got, until one was at length found in the mountains of Britain by a swineherd, which was brought down to the sea by Phileas, an engineer of Tauromenium. The ship was furnished with four anchors of wood and eight of iron, and though her sentena or sink was of so great size and depth, its one pump, by a device of Archimedes, was able to empty it managed by only one man. She had several tenders to accompany her, one whereof was a galley called the Cercurus, and the rest fishing boats and other small vessels. Her whole company was a great multitude, there being on the forecastle alone six hundred seamen always in readiness to execute such orders as should be given. The power of punishing all faults and misdemeanors done on board was committed to the captain, master, and master's mate, who gave sentence according to the laws of Syracuse. There were put on board of her sixty thousand bushels of corn, ten thousand barrels of salt fish, twenty thousand barrels of flesh, and as many bales of goods and necessaries, besides all the provisions for her company. Hiero, or Hieron, finding all his harbors either very dangerous for a ship of so vast a burden or else not capable at all to receive her, came to the resolution of presenting her to Ptolemy, King of Egypt, to whom she was accordingly sent and towed in safety to Alexandria.

This Ptolemy, who was surnamed Philopater, was already possessed of two ships of extraordinary dimensions, of his own building, which will be described hereafter. After the arrival of the Syracuse at Alexandria, she was hauled on shore, and nothing further is recorded of her. We may add that Archimelus, a Greek epigrammatist, wrote a little poem on the large vessel, which was rewarded by Hiero with a present to its talented author of one thousand measures of corn—a premium proportioned, if not to the poem, at least to the magnitude of the theme celebrated.

THE ISIS.—Still earlier than this hulk of Ptolemy's was the Isis, built by the Egyptians. She was one hundred and eighty feet in length, forty-five feet in breadth, and forty-three in perpendicular height from the bottom of the pump well. This vessel did not differ materially in form or dimensions from an English first-rate built at the close of the last century, except that she was rather larger in proportion to her breadth of beam. Her tonnage has been calculated at one thousand nine hundred tons.

PTOLOMAUS PHILOPATER'S TWIN WAR SHIP.—The description of a grand and magnificent war ship built by Ptolmaus Philopater, king of the Grecian-Egyptian empire from 221 to 204 B. C., its construction, equipments, and process of launching it, etc., is furnished by Athenæus in his fifth book.* Her tonnage, builders' measurements, has been estimated at six thousand four hundred and forty-five tons, and her external bulk eight hundred and thirty thousand seven hundred cubic feet.

"Philopater built a ship with forty ranks of rowers, being two hundred and eighty cubits (five hundred and sixty English feet) in length and thirty-eight cubits (seventy-six feet) from one side to the other; and in height up to the gunwales it was forty-eight cubits (ninety-six feet), and from the highest part of the stern to the water line fifty-three cubits (one hundred and six feet); and it had four rudders, each thirty cubits (sixty feet) long; and oars for the thranitæ, the largest thirty-eight cubits (seventy-six feet) in length, which from having a lead in their handles, and because they were heavy in the part inside the ship, being accurately balanced, were, in spite of their bulk, very handy to use; and the ship had two heads and two sterns, and seven rostra or beaks, one of which was larger than all the rest, and the others were of smaller size, and some of them were fixed to the ears of the ship; and it had twelve undergirths to support the keel, each six hundred cubits in length. And it was well proportioned to a most extraordinary degree; and all the appointments of the vessel were admirable, for it had figures of animals in it not less than twelve cubits in size, both at the head and at the stern, and every part of it was inlaid and ornamented with figures in wax; and the space between the oars down to the very keel had a running pattern of ivy leaves and thyrsi; and there was a great store of every kind of equipment to supply all parts of the ship that might require any. And when it put to sea it held more than four thousand rowers and four hundred supernumeraries, and on the deck were three thousand marines, or at least two thousand eight hundred and fifty. And besides all these, there was a large body of men under the decks, and a vast quantity of provisions and supplies. The vessel was launched originally from a sort of framework, which was created and made out of the wood of fifty ships of five ranks of oars; and it was launched by the multitude with great acclamations and blowing of trumpets. But after that the Phenician devised a new method of launching it, having dug a trench under it equal to the ship itself in length, which he dug close to the harbor. In the trench he built props of solid stone five cubits deep, and across them he laid beams, running the whole width of the trench, at four cubits distance from each other; and then making a channel from the sea, he filled all the space which he had excavated with water, out of which he easily brought the ship by the aid of whatever men happened to be at hand; then closing the entrance which had been originally made, he drained the water off again by means of engines, and when this had been done the vessel rested securely on the aforementioned cross beams."

The Thalamegus, a river vessel, also built by Philopater, is described by Athenæus:

"Philopater also built a vessel for the river, which he called Thalamegus, or the carrier of his bed chamber, in length half a stadium (or three hundred feet English), and in width at the broadest part thirty cubits (sixty feet), and the height, together with the frame for the awning, was little short of forty cubits (eighty feet); and its appearance was not exactly like ships of war nor merchant vessels either, but it was something different from both on account of the necessity imposed by the depth of the river, for below it was flat and broad, but in its main hull it was high, and the parts at the extremity, and especially at the head, extended a sufficient length, so as to exhibit a very pretty and elegant sweep. This ship also had two heads and two sterns, and it rose to a considerable height above the water, as was necessary, because the waves in the river often rose very high. In the middle of its hull were constructed banqueting rooms and sleeping rooms, and everything else which may be convenient for living in, and around the ship were double corridors running about three sides, each of which was not less than five plethra in circumference. The arrangement of the lower one was like a peristyle, and that in the upper part was covered in and surrounded with walls and windows on all sides. When you first came into the vessel by the stern your eye was met by a colonnade open in front and surrounded by pillars, and opposite to it in the bow of the vessel there was a sort of proscenium covered in overhead. Again, in the same way, in the middle of the vessel, was another colonnade open behind, and an entrance of four folding doors led to it. Both on the right hand and on the left there were windows admitting a pleasant breeze. To these was joined a room of very large size, and that was adorned with pillars all around, and it was capable of containing twenty couches. The greater part of it was made of split cedar and of Milesian cypress, and the doors which were around it, being twenty in number, were put together with beams of citronwood having ivory ornaments. All the nails and fastenings which were visible were made of red brass, which had taken a polish like that of gold from the fire. The whole of the capitals of the pillars were of gold, and there was a sort of girdle on them having figures of animals beautifully carved in ivory more than a cubit (two feet) high, of which the workmanship was not so conspicuous as the exquisite beauty of the materials. There was a beautiful roof to the banqueting room, square, and made of cypress wood; its ornaments were all carved, having a golden face. Next to this banqueting chamber was a sleeping chamber holding seven couches, and to that there was joined a narrow passage, which separated the women's chamber from this one by the width of the hold. By the passage was a banqueting room holding nine couches, very like the large one in the sumptuousness of its furniture, and a bed chamber holding five couches. As to the rooms then on the first deck, this was the general appearance presented. But when you had ascended by the stairs, which were close to the before mentioned sleeping chamber, there was another chamber capable of containing five couches, having a vaulted oblong roof. Near it was a temple of Venus, in form like a rotunda, in which was a marble statue of the goddess. Opposite to this chamber was another banqueting room, very sumptuous, adorned all round with columns, for the columns were all made of Indian stone. Near to this banqueting room were sleeping chambers, with furniture and appointments corresponding to what has been already mentioned. As you went on toward the head of the vessel was another apartment dedicated to Bacchus, capable of holding thirteen couches, surrounded by pillars, having its cornices all gilt as far down as the epistyle, which ran round the room, but the roof corresponded to the character of the god. In it there was at the right hand a large cave constructed, the color of which was stone—for, in fact, it was made of real stone and gold—and in it were images placed of all the relations of the king made of the stone called lychnites. There was another banqueting room, very pleasant, above the roof of the greatest apartment, having an arrangement like that of a tent, so that some of it had no actual roof; but there were arched and vaulted beams running along the top at intervals, along which purple curtains were stretched whenever the vessel was in motion. After this there was an open chamber occupying the same room above that occupied by the portico before mentioned as being below, and a wind-

* See Bohn edition.

* See Bohn's edition, vol. iii.

ing ladder joined on to it leading to the secret walk, and a banqueting room capable of containing nine couches, constructed and furnished in the Egyptian style. Four round pillars were run up in it, with alternate tambours of white and black, all placed in parallel lines, and these heads were of round shape, and the whole of the figures round them were engraved like roses a little expanded. Round that part which is called the basket there were not tendrils and rough leaves, as is the case in Grecian pillars, but calyxes of the river lotus and the fruit of newly budding dates, and sometimes many other kinds of flowers were also represented. Under the roof of the capital, which lies upon the tambour where it joins on the head, there were ornaments like the flower leaves of the Egyptian bean intertwined together. This, then, is the way in which the Egyptians construct and ornament their pillars, and this is the way in which they variegate their walls with black and white bricks, and sometimes also they employ the stone which is called alabaster. There were many other ornaments all over the main hall of the vessel and over the center, and many other chambers and divisions in every part of it. The mast of this vessel was seventy cubits (one hundred and forty feet) in height, and it had a linen sail adorned with a purple fringe."

HEAVY TANK LOCOMOTIVES FOR THE INDIAN STATE RAILWAYS.

THE engines illustrated herewith were manufactured by Messrs. Neilson & Company, Hyde Park Locomotive Works, Glasgow, for the Mushaf Bolan section of the Northwest Indian State Railways, to the designs of Sir A. M. Rendell, Westminster. They are intended to work on gradients of 1 in 25, and will traverse curves of 600 ft. radius. The total weight of the engine in working order is over 92 tons, and as the greatest weight per axle is restricted to 17¼ tons, four pairs of coupled wheels are required to give the necessary adhesion for the cylinder power. The engine is capable of taking a load of 220 tons exclusive of its own weight up a grade of 1 in 25. In India the water in the tanks gets so hot that there is sometimes difficulty in feeding with the injectors; in addition, therefore, to one injector, a donkey pump capable of feeding the boiler with water at 180° is fitted to the engine.

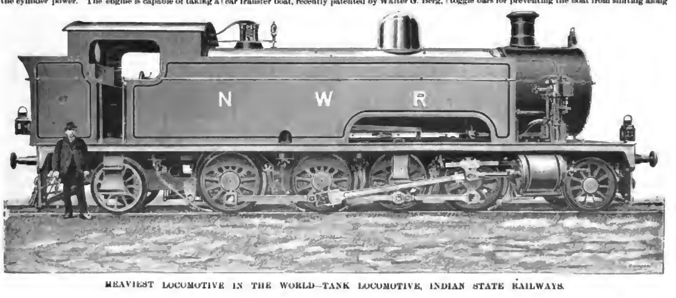
The principal dimensions of the engine are as follows:

Diameter of cylinders	20 in.
Length of stroke	26 in.
Diameter of coupled wheels	4 ft. 3 in.
	Square feet.
Heating surface in tubes	1942
Heating firebox	148
Total	2090
Area of fire grate	30·22
Contents of tanks	2300 gallons
Fuel space	190 cubic feet
Fixed wheel base	16 feet
Total wheel base	31 ft. 3 in.
Boiler pressure	180 lb. per sq. in.

Weight with tanks full, two tons of coal in bunkers, and in working order:

	Tons.	Cwts.	Qrs.
Leading radial	8	13	0
Leading coupled	17	8	1
Intermediate coupled	17	8	1
Driving	17	9	0
Trailing	17	6	3
Hind radial	13	16	2
	92	1	3

This is, we believe, the heaviest locomotive in the world.—The Engineer.

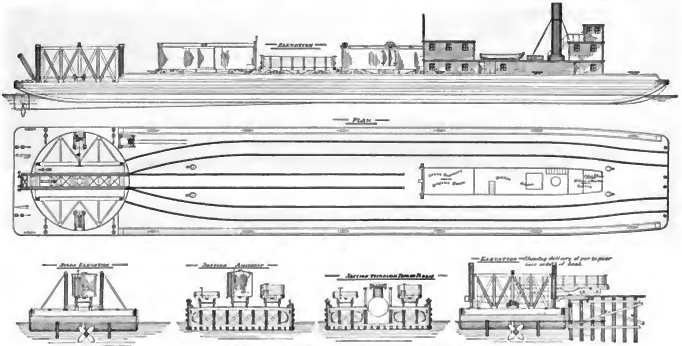


HEAVIEST LOCOMOTIVE IN THE WORLD—TANK LOCOMOTIVE, INDIAN STATE RAILWAYS.

BERG'S SPECIAL DELIVERY CAR TRANSFER STEAMER.

THE illustration represents a special construction of car transfer boat, recently patented by Walter G. Berg, member of the American Society of Civil Engineers, No. 261 West Fifty-second Street, New York City. The boat is provided with its own propelling machinery and with suitable mechanical appliances to allow a car on the boat to be raised to a proper height to be shunted ashore on a piece of track laid on the floor of the pier or bulkhead, which track need not be longer than necessary to hold a car or may be extended and carried into and through the consignee's establishment. By the special elevating and landing mechanism the car may be delivered either over the stern of the boat or on either side, cars being similarly transferred from land to the boat.

The illustration shows in plan, elevation and sectional views a transfer boat which may be made of a size suitable for ten or thirteen 38 ft. cars, each of 80,000 pounds capacity, in the latter case the boat being 38 ft. 6 in. wide and about 240 ft. long. The boat is to be propelled by a single screw driven by the usual class of marine engine and boiler at a speed of about ten miles an hour, and the extreme lift of the elevator is designed to be 10 ft. 6 in. As will be seen, the boat has on its deck three lines of railroad tracks, similar to those of the present car transfer boats, and at the stern of the boat is a turntable on which cars may be run from the tracks. The track on the turntable is supported by an independent platform that can be raised with the car on it above the deck of the boat, and lowered again to the deck of the boat at will. There is a swinging apron attached to one end of the platform, with suitable adjustable rail connections, etc., allowing a proper connection to be made with the rails of the track ashore. The turntable is designed to be turned by a wire rope winding drum, and the car may be moved along the deck to or from the turntable by rope haulage steam winch heads. The elevating platform will be raised by hydraulic power, working in cylinders on the turntable. The apron is raised, lowered, or locked in any position by special mechanism, and the boat is provided with chocking and chaining fixtures for holding the cars, locking latches for the turntable, toggle bars for preventing the boat from shifting along



SPECIAL DELIVERY CAR TRANSFER STEAMER.

United States Patent No. 576,941, February 9, 1897. Walter G. Berg, Patentee, 261 West Fifty-second Street, New York, N. Y.

the pier, and moving fixtures for tying up to the shore. It is designed that the crew, coal consumption, and operating supplies will be practically about the same as required on a regular large tug boat carrying the same class of propelling machinery.

INGLIS' TRIPLE EXPANSION PADDLE-WHEEL ENGINES.

WE illustrate herewith a type of triple expansion engines which Messrs. A. & J. Inglis, of Glasgow, have fitted to several paddle-wheel steamers during the past ten years, attaining, with each, a full measure of success consistent with the long record of the firm. The first steamer fitted was the Ramapoora, completed in 1887 for service in Indian waters. Since then four other large vessels have been fitted with similar engines, and the firm have just completed engines of 600 indicated horse power for two steamers for the River Steam Navigation Company, of Calcutta, and three others for small vessels abroad are in hand. As an indication of the relative space occupied, it may be said that these latter new engines will actually occupy less width athwartship than the old compound engines originally in the vessels.

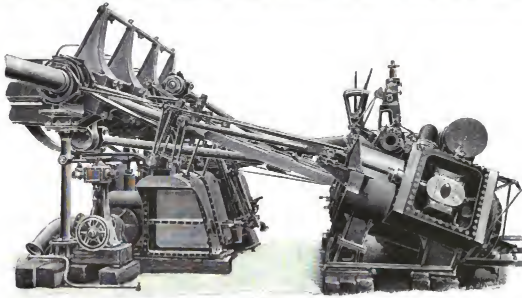


FIG. 1.

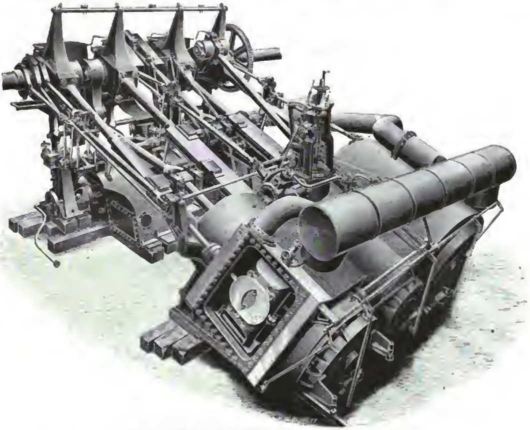

FIG. 2.—INGLIS TRIPLE-EXPANSION PADDLE ENGINES.

The engines illustrated are typical; since the first set was designed, only very slight alterations have been made. In the set placed in the Ramapoora the high pressure engine crank led, with the intermediate next, and the low pressure last; in subsequent cases the low pressure leads, followed by the intermediate and the high pressure. The practical results, either in respect of economy or efficiency, were not, however, affected by the change. In other respects the engines are identical. A noticeable point is that Messrs. Inglis have maintained their preference for the ordinary double eccentric motion, with Gooch's arrangement of stationary link, which has been so largely used in locomotive practice. To reverse the engine, the intermediate radius rod or link is shifted by means of the usual reversing shaft actuated by Brown's engine, so as to bring the quadrant block in line with the astern-going eccentric rod. It will be noticed that the suspension links oscillate on the reversing shaft as a center, and are coupled to the reversing quadrant at a point coincident with the attachment of the ahead-going eccentric rod. For an engine working generally in full gear ahead, this gives a smooth running gear with little motion of the block in the quadrant. Messrs. Inglis have adopted the Gooch stationary link gear for thirty years in paddle engines. It is interesting to note, in connection with the engines illustrated, that the firm have been able to get their triple engines into the steamer without adding to the space occupied by the compound engine, and that, too, without resorting to any but well tried gear.

The engines of the paddle steamer Paris, built for the Messageries Fluviales del Plata, and illustrated by us, occupied a width over the casing of 20 feet; they were designed to develop 2,500 indicated horse power while running at about 32 revolutions. The Rasmara was a repeat order of the Ramapoora, the second ship being completed in March of 1890. The Paris was the third paddle steamer fitted by Messrs. Inglis for the River Plate Company, the first two, the Helios and Triton, being built by the Scotswood Shipbuilding Company, Newcastle, in 1892 and 1894 respectively. The other vessels were constructed at the Pointhouse yard of Messrs. Inglis.

The cylinders are steam jacketed, and the high pressure is fitted with a piston valve receiving steam in the inside, while the intermediate and low pressure cylinders have double ported slide valves arranged, as shown, on the outside, so that they can be easily overhauled. The pistons are of steel, with a special packing adopted by the firm and arranged to give the least possible friction. The piston rods and valve spindles are fitted with metallic packing. The piston rods are made from Siemens-Martin steel ingots, but the connecting rods are of malleable iron. The main columns are of forged steel, and are made so as to form the guides for the piston rods. The entablature is of steel, and the construction can be seen by reference to the illustrations. These points, it may be said, indicate the usual practice at the Whitehall foundry of Messrs. Inglis. The crankshaft is in one piece and 16½ inches in diameter. It has long bearings of hard gun metal.

The wheel—arms and floats—is constructed of Siemens-Martin steel. The diameter is 21 feet over the floats, of which there are eight of 11 feet 6 inches width by 4 feet. Of course they are of the feathering type, and as is sometimes, although not invariably, the case with Messrs. Inglis' engines, there is no outer ring. This gives convenience in overhauling if it does not also minimize the repairs necessary after the wheel has collided with obstructions, when a ring is likely to get badly damaged.

The condenser is of cast iron and forms a support for the pumps and valve motion as shown. The tubes, ¾ inch in diameter, are of brass, and the tube plate, 1¼ inch thick, is of Muntz metal. The air pumps are brass and are worked from the high pressure crosshead. The circulating pumps are of the centrifugal type, by Gwynne, and are driven by a separate engine.

In connection with the Paris it is interesting to state, although it is not shown on the drawings, that the cylinders are fitted with a special cut-off gear, so that the cut-off may be as early as 10 inches to 12 inches of the stroke in the high pressure cylinder. This is arranged by a drop double beat valve, actuated by an eccentric and slip catches driven from the main shaft. It may be brought into use at any time, almost instantly, whenever it is desired to have an early cut-off.

The four boilers fitted are single ended, the diameter being 11 feet and the length 11 feet 3 inches. There are eight furnaces, 3 feet 6 inches in diameter inside measurement, and the tubes are 2¼ inches in diameter, the ratio of stay to fire tubes being 1 to 5. The grate area is 140 square feet and the heating surface 5,150 square feet. Howden's system of forced draught is fitted, and the boilers are arranged so that any two may be used independently of the others.

The trials of the Paris were conducted in midwinter in squally weather, with the ship fully loaded. The results given are the mean of four runs on the measured mile; indicated horse power, 2,200; revolutions, 32 per minute; speed, 16 knots. On a full power run 2,500 indicated horse power was exceeded.

To judge from the splendid finish of the saloons of the Paris, it is pretty evident that even in the unsettled regions which Europeans lump as South America, the trend is toward more luxurious surroundings afloat, and it is safe to assume that nothing like the Paris has as yet been seen on the Plate. Accommodation is provided chiefly for first-class passengers and for a few second-class. There are four decks — promenade, saloon, main and lower—and on the saloon and main decks one can accurately measure the advance on her predecessors which the new boat represents. The saloon deck shows the first-class Clyde shipbuilder at his best. The dining saloon and a large number of the staterooms are on this level, and, speaking broadly, the apartment from which access is obtained to them is the length and breadth of the ship. Amidships the engine space breaks the continuity, but forward of the obstruction there is a commodious and handsomely fitted dining saloon, and aft there is an apartment of similar size, which may be used as an auxiliary dining room, but will probably be utilized as what is termed on liners a "social hall." Wide corridors, in which are sofas and chairs, connect the two. The fittings throughout the ship are of the latest and most complete description, but on the saloon deck decorative art, as it is known in shipbuilding, is carried to very nearly perfection. The panelling is all in light wood, with hand-painted panels and a finely carved gilt cornice. The fanlights are also hand painted, and the glass panels of the stateroom doors are similarly treated. The sofas, chairs, etc., are upholstered in Utrecht velvet. There is a complete installation of electric light, so complete, indeed, that it supersedes even the candles on the piano in the forward saloon and in the organ in the after.

Among the novelties on board is a set of aluminum boats. The tackle blocks for lowering these are of the same metal, which is also largely used in some of the minor fittings usually classed as "ironmongery." Lightness and strength combined have been studied with unusual care, and to insure these qualities a large number of special sections of rolled steel have been employed in the construction.—Engineering.

INSECTICIDES AND HELPFUL AGENCIES.*

THE florist has his share of the insect world to fight; in fact it seems as though he had much more than his share, for insects multiply the year round, and so very rapidly in the warm and humid atmosphere necessary to forced plant growth. Many of the insecticides in use on the farm cannot be used on house plants, because the later are too delicate and tender. This has given rise to a great many patented insecticides, or remedies, composed of unknown ingredients which are sold under attractive names at fabulous prices. Many of them are valuable and worth the price, while others are valueless or worse than nothing. After all, there are usually simple, cheap and efficient remedies to which we return after our vain search for a panacea among the compound mixtures.

Water.—The florist appreciates the value of this simple and often very effective agent in insect control. In wetting the plants, a hose with a good nozzle attachment is used, so that the water can be thrown with force upon all parts of the plants, and so beat off many of the little pests that are lurking under the leaves or on the stems. More than this is rarely needed for the red spider, and many of the aleyrodes and male mealy bugs are also killed by this method.

In a home conservatory, or in the home where only a few plants are kept, the above method is rarely practicable, but hot water is even a better antidote for these troubles than cold. If once thoroughly tested, it will be found to be most valuable; it is always at one's command, costs nothing, and with a few moments' heating is ready for application. The plant is left clean and free from any bad effect if the water is not raised to too high a temperature. From 130° to 135° F. is sure death to most insects, while few plants are harmed by water at 150° F., the scalding point. Even the coleus, one of the most delicate of plants, is not injured by water at 150° F. On the more hardy plants, such as the cabbage, we know that water at 180° F. does them no harm. By the use of a thermometer, heat the water to 140° or 150° F., and then dip the plants into it quickly two or three times. If preferable, use a sprinkler or spray pump without a nozzle; but remember that the water must strike the insects to affect them, and to be effectual it must be at a temperature between 130° and 150° F. when it strikes them. Water cannot be thrown in a spray, as it cools too rapidly.

Tobacco.—There is perhaps no other substance in such general use for insects in the greenhouse, particularly the aphis, as tobacco in its various forms. The waste or hard parts of the tobacco leaves, known as "stems," can be obtained from cigar factories for almost no cost, and are quite as valuable an insecticide as the more expensive tobacco. The use of it as a smoke or vapor is the only practical method of application. When wanted for fumigating, the stems should not be so dry that they will blaze, but rather smolder and generate a large volume of smoke. They may be moistened at the time of using, but preferably should be kept in a moderately damp place where they will be evenly moistened throughout. Occasionally tobacco dust may be secured as cheaply as the stems, and for burning this will be found superior to the stems in some respects. Probably the best time to fumigate is late in the afternoon on a still day, as too much wind outside will usually drive the smoke to some extent inside. This, too, will leave the tobacco fumes in the house overnight, and the full effect will be derived from them. The tobacco may be burned in various ways. Some use sheet iron buckets for holding the tobacco, others place it on the earth or cement floor and burn it there. The Elmira (N. Y.) florist, Mr. Grove P. Rawson, writes that an occasional shovelful of live anthracite coals from the furnace spread over the tobacco dust serves him the best of anything. The amount of tobacco to be used and the frequency in using must be left largely with the operator in each individual case, as the kind of plant to be treated, the tightness of the house, the strength of tobacco, and the abundance and kind of insects all tend to vary the amount and time.

Within the past two or three years vaporized tobacco has largely superseded tobacco fumes. By those who have tested both, the vapor is considered much superior and more effective on the aphis. Where steam is used for heating, the treatment is very simple. The tobacco stems are placed in a kettle or barrel; a hose is then connected with one of the steam pipes, the other end is inserted into the kettle, and the steam does the rest. The house is very quickly saturated with the tobacco vapor and the work soon over. Surplus moisture of course is the item to be feared in this treatment, and to prevent mildew, florists are generally agreed that the treatment should be given early in the morning on a bright day, and as soon as it is finished the plants should have their regular syringing and the house be ventilated.

Another method of vaporizing that has many adherents is to apply liquid tobacco directly to the outer surface of the steam pipes and allow it to evaporate. The Louisville Spirit-Cured Tobacco Company, of Louisville, Kentucky, recommend this method for the use of their liquid tobacco extract, and it has given excellent satisfaction as far as we have been able to ascertain.

Our college greenhouse is heated by hot water, and with us the vaporization of tobacco is not as practicable as fumigation, owing to the pipes remaining at too low a temperature. A fair substitute for steam is a hot brick dropped into the liquid extract. Evaporating over an oil stove is too slow to be recommended.

Kerosene Emulsion.—For the hardy ornamental plants out of doors and the more hardy ones indoors, kerosene emulsion may be used. On the more delicate plants it must be used with great caution, if at all. There is quite a question in the mind of the author whether it should be even recommended when there are other good and safer oil and soap washes that may be substituted.

For those who care to use the emulsion, the following formula may be followed:

Soft Soap Formula.—Heat a gallon of soft soap until it becomes liquid; then take from the fire, add two quarts of kerosene and agitate for three or five minutes so thoroughly that the soap and oil become permanently mixed—that is, until the oil will not separate from the soap either on standing or when diluted. A hand force pump should be used in making the emulsion. Slow pumping or stirring with a stick or spoon will not emulsify the soap and oil.

The emulsion as made is now one third oil, and for the plants it should be only one-fifteenth oil. So it will need four times its own bulk of water before using. In other words, the gallon of soap and two quarts of oil will make seven and one-half gallons of the dilute emulsion.

If the emulsion is to be made in the above or greater quantity, it should always be made with soft soap, if that is obtainable, as the emulsion is more difficult to make by the hard soap formula, where more water is required.

Hard Soap Formula.—To two quarts of water add one fourth pound of hard soap, heat to the boiling point, and when the soap is dissolved add the pint of kerosene and proceed as in the soft soap formula. This is one-fifth oil and should be diluted with twice its own bulk of water before using.

Fir Tree Oil.—This is a penetrating oily liquid which is one of the best insecticides that we have found for such insects as the mealy bug, thrips, red spider, aleyrodes, and young scale. It can be procured through florists or dealers in florists' goods. The cost is one dollar per quart. This is rather high priced, but when one has but a few plants the treatment will not be expensive. When used at the rate of one-half pint to a gallon of water there is danger of injuring the most delicate plants. At the rate of two-thirds of a pint to a gallon of water ferns are the only plants on which we have tested it that are injured. This last proportion is much more effective on mealy bugs and aleyrodes than the weaker mixtures. One of the great pleasures derived from the use of this mixture, besides that of killing the insects, is the fine condition in which it leaves the foliage. There is a bright, clean luster that reminds one of new foliage.

Some florists apply the undiluted oil on the scale insects with a small brush and find it very successful, though a little slow.

Fir Tree Oil Soap.—This is a soap prepared from the fir tree oil and is sold, as far as we know, only by J. C. Pierson, of Newark, N. J. It has all the qualities of the fir tree oil, and, if anything, can be used stronger on the plants than the oil without injury to them. It should be used from three to five times as strong as recommended by the agency to secure the best effect, or, in other words, from three to five ounces to each gallon of water. This makes the expense about ten to fifteen cents per gallon, which is, at that strength, less than the cost of the oil. The soap dissolves readily in soft water upon heating slightly, and leaves the foliage with a glossy luster.

Whale Oil Soap.—We used the whale oil soap in comparison with the last two substances, and find that, while it is much cheaper than either of them, it is also inferior in several respects. If made strong enough to be as destructive to insect life, it is more liable to injure the foliage of the more tender plants, and when used very strong it leaves the foliage more dirty and with white, soapy, mildewlike spots on the leaves. When used at the rate of one-fourth pound to a gallon of water there was no injury to plants; one-half pound to a gallon injured the foliage of several tender plants.

Soft water should be used with all of these soap and oil washes.

Cole's "Insect Destroyer."—Professor Comstock says of this in the United States Agricultural Report for 1880: "An analysis of it shows that it may be closely copied by dissolving 2 to 2·5 per cent. of green soap in 100 parts of 50 per cent. alcohol." The material is prepared ready for use when purchased, and is sprayed upon the insects with a hand atomizer. It is harmless to the plant, but we have found it rather inferior to the oil and soap washes in its effect upon mealy bug and young scale. When applied, appearances would lead one to think that the destruction of insects was complete, but a later examination will show that quite a share of them recover. The cost is about ninety cents or a dollar a pint.

Hydrocyanic Gas.—At present we cannot recommend its use, except with the greatest caution. One should also remember that it is a strong poison.

Bisulphide of Carbon.—Very good success has been attained in treating red spider and aphis with this gas. Were there not other remedies simpler, cheaper and as effective on these insects, it would no doubt form one of our valuable greenhouse insecticides. As it is, there is too much risk to run from injury to the plants in treating them in this way for the extra benefit derived over tobacco vapor for the aphis, and water or the oil and soap washes for the red spider. To be used on plants they must be placed in a tight box, barrel, or other receptacle. The bisulphide is then introduced in a shallow dish or on cotton batting at the rate of about nine or ten drops per cubic foot of space. Keep the box closed for about two hours.

Flowers of Sulphur.—As a partial insecticide and a good fungicide, sulphur is a desirable substance to use in the greenhouse. It is also destructive to plant life when too much is used, and hence care and experience are needed in its use. Some florists claim good results on red spider from a small quantity of sulphur dropped on a hot shovel and held beneath the mite-infested plant until the odor becomes strong in that vicinity. The usual method is to mix with an equal bulk of air-slaked lime, make it into a thick paste by addition of water, and then spread upon the heating pipes or furnaces.

Lime.—For insects that live in the soil and feed on the roots of plants, alkaline substances, such as air-slaked lime or wood ashes mixed with the soil, give very satisfactory results. They are also considered among the most valuable remedies against eel worms and slugs. Florists differ as to the amount that gives the best results, the range being from a coating an inch thick to a slight white covering of the soil. A conservative average, or less than half an inch coating, would seem nearest right, but this depends greatly upon the depth of the soil on the benches. The lime should be thoroughly mixed with the soil before transplanting to it.

Wood Ashes and Soot.—These substances are good substitutes for air-slaked lime when unleached, but in a fresh state they cannot be used as freely in the soil. Even if they are of no direct benefit in repelling insects, they are of indirect value in supplying potash.

Paris Green.—There are a few insects on house plants against which we can use the arsenites with good effect. Paris green is less apt to injure the foliage than the other arsenites, as there is less soluble arsenic in it. A quarter of an ounce to three gallons of water is as strong as it should be used. If a little strong lime water is added, there will be no danger of injuring tender plants, as all the arsenic in the Paris green then becomes insoluble.

Toads.—The toad is a great insect destroyer and is well worthy the protection of florists. He is actively engaged in catching his prey throughout almost the entire year, and as his work is done mostly at night and on cloudy days, he catches a great many of the night marauders, such as slugs, millipeds, and cutworms. All that he needs is a small pile of loose soil in which to burrow and a cool place under the bench in which to retreat.—Bulletin of Pharmacy.

* Excerpt from Special Bulletin No. 2, Michigan Agricultural College.

Buyers and users of metal roofing and siding have had a tendency toward lighter gages in recent years. This is probably due to the smaller cost and is in line with the general disposition for lower priced goods, even when the difference is very slight. Two gages are now in common use, Nos. 28 and 28, with only infrequent demand for No. 27, but I think that most manufacturers would recommend the use of No. 24 if it were not for the tendency in question. The added cost is not material when the extra weight and wearing qualities are considered. At the same time that lighter gages came in vogue there was noted an increased movement in favor of galvanized sheets and a change from iron to steel, while these are really the most marked changes that have been made in this branch of roofing in the past ten years. Metallic lathing has been introduced in that time, but this is an individual branch of the business and has no direct bearing on the other question.—Stoves and Hardware Reporter.

ELECTRICAL NOTES.

The King of Siam has granted a franchise for an electric lighting plant in Bangkak to an American firm.

The Russian Electro-technical Association will hold an International Electrical Exhibition in St. Petersburg during the summer of 1899. All the principal electro-technical industrial concerns will be invited to participate in the exhibition, for which considerable success is foreshadowed.

Belgrade, the capital of Servia, is now to be supplied with a system of telephone lines. Four hundred customers have already subscribed, and the construction will shortly be taken up by the firm of I. Berliner, of Vienna, who, out of several applicants, have been successful in securing the contract.—Electrotechnische Rundschau.

A Reuter telegram states that during a thunder storm which passed over the district of Rosenheim, Bavaria, recently, a powder factory near Stephanskirchen was struck by lightning. A large quantity of powder, amounting to 11,000 lb., exploded, and 11 houses were shattered. The force of the explosion was such that large trees were torn up by the roots. In Rosenheim, which is about four miles distant from the scene of the explosion, and in Stephanskirchen, which is over a mile off, doors were burst from their hinges and windows from their frames, and in some cases broken. Only one workman at the factory is said to have been injured, and that not seriously.

A large electric installation has recently been completed at Rovos, Norway, says Engineering. There are two large alternate current dynamos, with a tension of 5,000 volts. The dynamos are directly coupled with the turbines, each of 300 horse power. The current is conveyed from the machinery house by means of bright copper wires to three copper mines, some 5 to 7 miles distant, and is there transformed to 150 volts. The electricity is used both for lighting purposes and for working a considerable amount of machinery. A separate dynamo supplies the requisite electricity for the electric railways. Every precaution has been taken to prevent accidents, the wires being protected where the surroundings make this necessary. The height of the fall is about 50 ft.

United States Consul Morris, writing from Ghent, April 16, gives details of the proposed construction of an electric street railway system in that city. The franchise includes all the lines proposed for the entire city, and will be sold to the highest bidder at a fixed annual rental to be paid to the city for a certain term of years, at the expiration of which the city reserves the privilege of purchasing the entire system. The motive power will be electricity, the accumulator to be used in the central portion of the city, and in the outlying districts the trolley system. The fare for first class passengers will be three cents and for second class two cents. The employes will work from thirteen and a half to fourteen and a half hours a day, and the wages for motormen, conductors and workmen are fixed at 72, 69½, and 58 cents per day, respectively. The final award of the franchise will be made on or about July 1.

Capt. Lampe, of the steamship Leon, which arrived at New York City recently with fruit from Jamaican ports, tells a story of a remarkable electric storm encountered while his vessel was off Cape Hatteras. The steamer, according to the skipper's story, was plowing along through a smooth sea, with clear weather overhead, when suddenly, with scarcely any barometric warning, jet black clouds gathered on the horizon, and with almost incredible swiftness mounted into the heavens, accompanied by the constant and terrific booming of thunder and flashes of lightning. The three women passengers on the steamer were almost hysterical from fright. For almost five hours the little vessel groped her way along. All the time the sea was as smooth as glass. The climax of the storm occurred when a great bolt of lightning shot over the bow of the Leon and struck the water fifty yards away with terrific force. An immense volume of water was thrown into the air to a height of fifty feet, deluging the deck of the steamship with spray. Then the rain fell in torrents. The officers of the Leon believe that the water that fell on the vessel was from a cloudburst. The water came, not in drops, but in sheets and columns. The crew were unable to stand the deluge on deck, and all hands were ordered below. Suddenly the clouds lifted, and within a short time there were left the usual summer sky and sea.

A writer in the Iron Age speaks of the trolley as a "dangerous feature for the smaller dealers" in hardware, because it enables the farmer, who was formerly tied down to the general local store, to reach easily the larger centers of trade. "It did not pay the inhabitants of small cities to spend $3 to $4 for the purpose of purchasing about the same amount in a large neighboring city, especially when the number of trains was limited, and when it consumed a whole day and well into the night to make the journey. But now the electric car stops at the farmer's door, suburban cars leave every thirty minutes, they carry express packages, and they take much of the local trade to neighboring cities. The small country dealer is the greatest sufferer. He loses his cash customer and retains those whom he has to carry and who have no ready money. The larger towns gain from the country what trade they lose to the cities, while the cities have nothing to lose." It strikes us from a different point of view. The very fact that the trolley cars deliver express packages should enable the small general store in a village to carry practically a much larger stock than ever before and to fill many wants that previously were not felt or went unsatisfied because of the distance from market. Besides, accessibility always promotes trade and intercourse, and this ought to be a good thing for the small country dealer, particularly if the trolley brings into his neighborhood a number of residents, earning good weekly cash salaries, to whom the real country was formerly out of reach. Heretofore the small dealer has presumed on his inaccessibility, and made it an excuse for not handling a number of useful and desirable things. The trolley gives him a genuine opportunity of new life. But if he supinely lies down to die, he will die before he is dead, and someone else will see the modern chances and find a profitable way out.

MISCELLANEOUS NOTES.

The United States of Brazil issued 200 patents in 1896, of which 111 were secured by Brazilians, 22 by Americans, the same number by Englishmen, 16 by Frenchmen, and 14 by Germans.—La Propriété Industrielle.

Mulhausen (Alsace) shows a remarkable increase in population; in the 20 years from 1875–1895, the number of inhabitants has risen from 58,463 to 83,040, i. e., 42 per cent. This is mainly due to the growth of the manufactures, and a correspondingly increased demand for workmen.—Uhland's Wochenschrift.

Mr. Venukoff informs the Geographic Society of Paris that the Araxes (Transcaucasia), restored to its ancient course, now flows directly into the Caspian Sea, and is thus no longer a tributary of the Kura. As this change is considered favorable by the inhabitants, the government has been requested to take measures to render the present state of things permanent.—Die Umschau.

Hitherto calcium carbide was prepared by fusing lime and coke together in a Moissan and Willson electric furnace. But this process, even if the required force can be supplied by a watercourse, is rather costly, so that a cheaper process, patented by Pictet, is likely to prove very useful. He introduces the lime and coke in a furnace and acts with the electric arc at the bottom only. The coke begins to burn, and, by the aid of a blast of hot air, raises the whole mass to a very high temperature, so that but little additional heating on the part of the arc is required. This improvement is of great importance, because it will make acetylene a dangerous rival to our ordinary coal gas, which it far exceeds in luminosity.—Electrotechnische Rundschau.

A patent has been applied for in Belgium for an incombustible lampwick. This is made of glass, and it is traversed by fine channels. The lamp is lit automatically, the oil being drawn up the channels by atmospheric pressure. It is urged as one of the main advantages of the invention, besides the incombustibility of the burner, that the supply of oil is uniform, so that a flickering flame and the result of such, the cracking of chimneys, are avoided. It seems, however, that on the one hand the making of such wicks offers difficulties, and on the other even refined kerosene oil leaves solid residues which would in time stop up the pores, and danger of explosion would arise.—Uhland's Wochenschrift.

We give a description of a new procedure for condensing milk into a semi solid or a powder.

The milk is first frozen, being continually kept in motion, so that the ice crystals may separate out. By means of a centrifugal separator the milk is then obtained free from ice. This process is repeated until the product contains 80–85 per cent. solid constituents. The milk is then sterilized and concentrated in vacuo at a temperature of 38° Centigrade. Into the vacuum carbon dioxide is admitted, and the pasty mass is cast into forms. When solid it is hacked up, finally dried in carbon dioxide, cooled to 0° Centigrade, and powdered. The powder is packed in hermetically sealed jars which contain carbon dioxide.—Uhland's Wochenschrift.

An immense block of granite, having a given weight of not less than 1,217 tons, was recently put in place at St. Petersburg as the pedestal for the new statue of Peter the Great, the block having been transported four miles by land over a railway and thirteen miles in a caisson by water. The railway consisted of two lines of timber furnished with hard metal grooves, between which grooves were placed spheres of hard brass about six inches in diameter; on these spheres the frame with its load was easily moved by a force of sixty men working at the capstans with treble purchase blocks. Another large block, measuring thirty-five by sixteen by fourteen feet, is reported to have been taken out, a few months since, from the Craigneth quarries, near Dalbeattie, Scotland, the block weighing 650 tons.

Wm. W. Astor entertained his guests at a dinner in London, England, not long ago, with stories of the big trees in California. Some of his hearers professed to be skeptical, whereat Mr. Astor offered to wager that he could have prepared from one cross section of a California tree a table sufficiently large to accommodate at dinner the forty guests then assembled, or others to that number. The wager was accepted. The sequel is transpiring. There was shipped at San Francisco recently a redwood section, cut from a tree 14 ft. 4 in. in diameter, consigned to "W. W. Astor, London, England." The piece of timber is 8 ft. thick and weighs 19 tons. Given time, and safe voyage to the good ship, Mr. Astor will entertain forty or more guests around a table constructed of this product of the forests of Humboldt County, Cal., and win his wager, at the same time impressing an object lesson on his insular cousins to the glorification of the United States.

A demonstration of the fire resisting properties of timber, prepared in accordance with a process recently patented in America, has been given in England. Two small houses, each of identical shape and dimensions, and fitted with wooden chimneys, but constructed in the one case of ordinary and in the other of treated timber, were exposed to the flames of a large bonfire piled against the windward side of each of the two buildings. The first named caught fire immediately, and collapsed in the course of half an hour, while the other stood the ordeal almost unharmed. Finally, a second fire was lighted inside this building, the chimney of which created a fierce draught. The structure, however, remained quite intact, and the wood, though it charred somewhat, entirely refused to burst into flame. The treatment consists in first thoroughly desiccating the timber in vacuo and then impregnating it under pressure with certain salts, the nature of which was not disclosed. The appearance of the timber and its working qualities are scarcely affected. In fact, it takes a polish somewhat more readily after treatment than before, as the pores of the timber are filled in the process. The battle of Yalu showed the importance of abolishing inflammable material on board warships, while the comfort of the officers and crew are equally bound up in the maintenance of a wood finish for their quarters. If the expense of the process does not prove prohibitive, a fairly large field should, we think, be open to it in this direction, and we note that it has been adopted somewhat extensively by the government of the United States.

SELECTED FORMULÆ.

The Preservation of Animals.—In a recent number of Natural Science there is given a summary of the observations of Mr. Amyrald Haly, director of the museum of Colombo, upon the value of formaline as an agent for preserving zoological specimens. According to Mr. Haly, who has been using this material for the last two years, a 1½ or 2 per cent. solution suffices to preserve the invertebrates in general. For the vertebrates it requires a 3 or 3½ per cent. solution. Formaline preserves the Medusæ admirably, their colors and transparency remaining unchanged. Mr. Haly confesses, however, that formaline is not of universal application, for sometimes it fails. For fish of bright colors it is better to use gum and glycerine, and the same is the case with crustacea; but perhaps gum and formaline mixed might be used with advantage.

Cleansing Fluid for Aluminum Ware.—A solution of 30 grammes of borax in 1 liter of water containing a few drops of aqua ammonia.

Varnish for Aluminum Bronze.—The liquid which is sold in the United States under the trade name of the light Japan gold size is the best varnish to use with powdered aluminum bronze. This, however, is not the same article as is sold in England under the name of the gold size, and the best of these varnishes is made by taking 50 pounds of Kauri and 50 pounds of Zanzibar resin, together with 5 gallons of refined linseed oil, cooking these at a high temperature until there is no free oil left. This mixture should then be thinned down with a proper amount of turpentine (about 25 or 30 gallons), and then a drier should be added.—Aluminum World.

Preserving Tomatoes.—Take the best, firmest, and not over-ripe fruits, scald and skin carefully, take the stem out with a penknife, being careful not to cut the tomato and let the juice out; place in a jar, some with the stem and some with the flower end next to the glass. Cook some juice, adding a little salt, and pour over the whole tomatoes until the jar is nearly full. Place the jars in a common fish boiler of oblong shape, with a cloth at the bottom to protect them from the heat of the fire, which is liable to crack them. Fill the boiler with cold water and bring to nearly boiling point, or sufficient to heat the tomatoes clear through, and seal the jars. In about five minutes take off the jar cover to let gas out and allow the tomatoes to settle; then fill up with boiled juice and seal again. Next day screw the tops tight and put away in a dark, cool place.—Agricult. Journ., x, 330.

Insecticide for Plant Lice.—An effective insecticide for various insect pests on greenhouse plants is composed of the following:

Take of

Methylated spirit	200	parts.
Soft soap	20	"
Quassia wood	6	"
Salicylic acid	2½	"

Macerate for several days; dilute with sufficient water, and apply to the infested parts by means of a brush. Allow to dry on; the following day wash off with plenty of water.—Rev. Méd. Pharm.

Antiseptic Mouth Wash.—The Presse Médicale contains the following formula:

Thymol	4	gr.
Benzoic acid	14	"
Tincture of eucalyptus	225	"
Essence of peppermint	9	"
Chloroform	15	"
Alcohol	3	"

M. Twenty drops of this solution in a glass of water may be used at a time.

Mothol.—A pleasant deodorizer and moth preventive.

Alcohol	40	oz.
Tincture of capsicum	5	"
Naphthalene	1	"
Absolute phenol	1	"
Menthol	⅛	"
Oil of lemongrass	⅛	"

Mix and filter. To be used in the form of spray by means of an atomizer where the moths frequent.—Bulletin of Pharmacy.

Photographic Hints and Formulas.—

From Liesegang's Photographischer Almanach.—(Amer. Photo. Jl.)

Chalk Bath.—

Water	100 c. cm.
Chloro-aurate of potassium	1 grm.

For use—

Above solution	10 c. cm.
Water	115 "
Whitening	1 grm.

Mix and shake thoroughly at least twelve hours before use.

Toning Bath (Acetate of Soda).—

Water	2 liters.
Chloride of gold	1 grm.
Acetate of soda	30 "

Crystallized acetate of soda gives warm red tones; fused, bluish tones. The latter bath must be made up twenty-four hours before use.

Toning Bath (Borax).—

Water	1 liter.
Borax (fused)	8 grm.
Chloride of gold	1 "

Toning Bath (Chloride of Lime).—

Acetate of potassium	12 grm.
Chloride of lime	3 "
Carbonate of potash	6 "
Distilled or boiled water	480 c. cm.

Above is to be well shaken, then allowed to settle, decanted and filtered through cotton.

For use—

Above stock solution	320 c. cm.
Distilled or boiled water	3 liters.
Chloride of gold	1 grm.

This bath keeps well and may be used until the gold is entirely exhausted. Prints should be printed up strong.

SIGNALING THROUGH SPACE WITHOUT WIRES.*

By W. H. PREECE, C.B., F.R.S.

SCIENCE has conferred one great benefit on mankind. It has supplied us with a new sense. We can now see the invisible, hear the inaudible, and feel the intangible. We know that the universe is filled with a homogeneous continuous elastic medium which transmits heat, light, electricity, and other forms of energy from one point of space to another without loss. The discovery of the real existence of this "ether" is one of the great scientific events of the Victorian era. Its character and mechanism are not yet known by us. All attempts to "invent" a perfect ether have proved beyond the mental power of the highest intellects. We can only say with Lord Salisbury that the ether is the nominative case to the verb "to undulate." We must be content with a knowledge of the fact that it was created in the beginning for the transmission of energy in all its forms, that it transmits these energies in definite ways and with a known velocity, that it is perfect of its kind, but that it still remains as inscrutable as gravity or life itself.

Any disturbance of the ether must originate with some disturbance of matter. An explosion, cyclone or vibratory motion may occur in the photosphere of the sun. A disturbance or wave is impressed on the ether. It is propagated in straight lines through space. It falls on Jupiter, Venus, the earth, and every other planet met with in its course, and any machine, human or mechanical, capable of responding to its undulations indicates its presence. Thus the eye supplies the sensation of light, the skin is sensitive to heat, the galvanometer indicates electricity, the magnetometer shows disturbances in the earth's magnetic field. One of the greatest scientific achievements of our generation is the magnificent generalization of Clerk-Maxwell that all these disturbances are of precisely the same kind, and that they differ only in degree. Light is an electromagnetic phenomenon, and electricity in its progress through space follows the laws of optics. Hertz proved this experimentally, and few of us who heard it will forget the admirable lecture on "The Work of Hertz" given in this hall by Prof. Oliver Lodge three years ago.

By the kindness of Prof. Silvanus Thompson I am able to illustrate wave transmission by a very beautiful apparatus devised by him. At one end we have the transmitter or oscillator, which is a heavy suspended mass to which a blow or impulse is given, and which, in consequence, vibrates a given number of times per minute. At the other end is the receiver, or resonator, timed to vibrate to the same period. Connecting the two together is a row of leaden balls suspended so that each ball gives a portion of its energy at each oscillation to the next in the series. Each ball vibrates at right angles to or athwart the line of propagation of the wave, and as they vibrate in different phases you will see that a wave is transmitted from the transmitter to the receiver. The receiver takes up these vibrations and responds in sympathy with the transmitter. Here we have a visible illustration of that which is absolutely invisible. The wave you see differs from a wave of light or of electricity only in its length or in its frequency. Electric waves vary from units per second in long submarine cables to millions per second when excited by Hertz's method. Light waves vary per second between 400,000,000,000 in the red to 800,000,000,000 in the violet, and electric waves differ from them in no other respect. They are reflected, refracted, and polarized, they are subject to interference, and they move through the ether in straight lines with the same velocity, viz., 186,400 miles per second—a number easily recalled when we remember that it was in the year 1864 that Maxwell made his famous discovery of the identity of light and electric waves.

Electric waves, however, differ from light waves in this, that we have also to regard the direction at right angles to the line of propagation of the wave. The model gives an illustration of that which happens along a line of electric force; the other line of motion I speak of is a circle around the point of disturbance, and these are called lines of magnetic force. The natural eye is tuned to one series of waves, the "electric eye," as Lord Kelvin called Hertz's resonator, to another. If electric waves could be reduced in length to the forty-thousandth of an inch, we should see them as colors.

One more definition and our ground is cleared. When electricity is found stored up in a potential state in the molecules of a dielectric like air, glass or gutta percha, the molecules are strained, it is called a charge, and it establishes in its neighborhood an electric field. When it is active or in its kinetic state in a circuit, it is called a current. It is found in both states, kinetic and potential, when a current is maintained in a conductor. The surrounding neighborhood is then found in a state of stress, forming what is called a magnetic field.

In the first case the charges can be made to rise and fall and to surge to and fro with rhythmic regularity, exciting electric waves along each line of electric force, at very high frequencies, and in the second case the currents can rise or alternate in direction with the same regularity, but with very different frequency, and originate electromagnetic waves whose wave fronts are propagated in the same direction.

The first is the method of Hertz, which has recently been turned to practical account by Mr. Marconi, and the second is the method which I have been applying, and which, for historical reasons, I will describe to you first.

In 1884 messages sent through insulated wires buried in iron pipes in the streets of London were read upon telephone circuits, erected on poles above the housetops 80 feet away. Ordinary telegraph circuits were found in 1885 to produce disturbances 2,000 feet away. Distinct speech by telephone was carried on through one-quarter of a mile, a distance that was increased to 1½ miles at a later date. Careful experiments were made in 1886 and 1887 to prove that these effects were due to pure electromagnetic waves and were entirely free from any earth conduction. In 1892 distinct messages were sent across a portion of the Bristol Channel, between Penarth and Flat Holm, a distance of 3·3 miles.

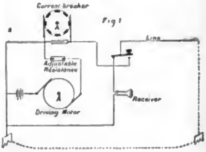
Early in 1895 the cable between Oban and the Isle of Mull broke down, and as no ship was available for repairing and restoring communication, communication was established by utilizing parallel wires on each side of the channel and transmitting signals across this space by these electromagnetic waves.

The apparatus (Fig. 1) connected to each wire consists of: (a) A rheotome or make and break wheel, causing about 260 undulations per second in the primary wire. (b) An ordinary battery of about 100 Leclanche cells, of the so-called dry and portable form. (c) A Morse telegraph key. (d) A telephone to act as receiver. (e) A switch to start and stop the rheotome. Good signals depend more on the rapid rise and fall of the primary current than on the amount of energy thrown into vibration. 260 vibrations per second give a pleasant note to the ear, easily read when broken up by the key into dots and dashes.

In my electromagnetic system two parallel circuits are established, one on each side of a channel or bank of a river, each circuit becoming successively the primary and secondary of an induction system, according to the direction in which the signals are being sent. Strong alternating or vibrating currents of electricity are transmitted in the first circuit so as to form signals, letters, and words in Morse characters. The effects of the rise and fall of these currents are transmitted as electromagnet waves through the intervening space, and if the secondary circuit is so situated as to be washed by these ethereal waves, their energy is transformed into secondary currents in the second circuit, which can be made to affect a telephone, and thus to reproduce the signals. Of course their intensity is much reduced, but still their presence has been detected, though five miles of clear space have separated the two circuits.

Such effects have been known scientifically in the laboratory since the days of Faraday and of Henry, but it is only within the last few years that I have been able to utilize them practically through considerable distances. This has been rendered possible through the introduction of the telephone.

Last year—August, 1896—an effort was made to establish communication with the North Sandhead (Goodwin) Lightship. The apparatus used was manufactured by Messrs. Evershed & Vignoles, and a most ingenious relay to establish a call was invented by Mr. Evershed. One extremity of the cable was coiled in a ring on the bottom of the sea, embracing the whole area over which the lightship swept while swinging to the tide, and the other end was connected with the shore. The ship was surrounded above the water line with another coil. The two coils were separated by a mean distance of about 200 fathoms, but communication was found to be impracticable. The screening effect of the sea water and the effect of the iron hull of the ship absorbed practically all the energy of the currents in the coiled cable, and the effects on board, though perceptible, were very trifling—too minute for signaling. Previous experiments had failed to show the extremely rapid rate at which energy is absorbed with the depth or thickness of sea water. The energy is absorbed in forming eddy currents. Although this experiment has failed through water, it is thoroughly practical through air to considerable distances, where it is possible to insert wires of similar length on each side of the distance to be crossed. It is not always possible, however, to do this, nor to get the requisite height to secure the best effect. It is impossible on a lightship, and on rock lighthouses. There are many small islands—Sark, for example—where it cannot be done.



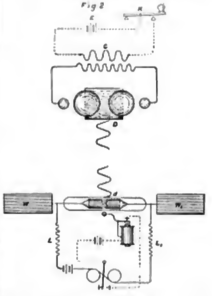
In July last Mr. Marconi brought to England a new plan. My plan is based entirely on utilizing electromagnetic waves of very low frequency. It depends essentially on the rise and fall of currents in the primary wire. Mr. Marconi utilizes electric or Hertzian waves of very high frequency, and they depend upon the rise and fall of electric force in a sphere or spheres. He has invented a new relay which, for sensitiveness and delicacy, exceeds all known electrical apparatus.

The peculiarity of Mr. Marconi's system is that, apart from the ordinary connecting wires of the apparatus, conductors of very moderate length only are needed, and even these can be dispensed with if reflectors are used.

The Transmitter.—His transmitter is Prof. Righi's form of Hertz's radiator—see Fig. 2. Two spheres of solid brass, 4 in. in diameter—A and B—are fixed in an oil tight case of insulating material, so that a hemisphere of each is exposed, the other hemisphere being immersed in a bath of vaseline oil. The use of oil has several advantages. It maintains the surfaces of the spheres electrically clean, avoiding the frequent polishing required by Hertz's exposed balls. It impresses on the waves excited by these spheres a uniform and constant form. It tends to reduce the wave lengths—Righi's waves are measured in centimeters, while Hertz's were measured in meters. For these reasons the distance at which effects are produced is increased. Mr. Marconi uses generally waves of about 120 centimeters long. Two small spheres, a and b, are fixed close to the large spheres and connected each to one end of the secondary circuit of the "induction coil," C, the primary circuit of which is excited by a battery, E, thrown in and out of circuit by the Morse key, K. Now, whenever the key, K, is depressed sparks pass between 1, 2 and 3, and since the system, A B, contains capacity and electric inertia, oscillations are set up in it of extreme rapidity. The line of propagation is Dd, —Fig. 2—and the frequency of oscillation is probably

WILLIAM MARCONI, INVENTOR OF THE APPARATUS FOR TELEGRAPHING WITHOUT WIRES.

Fig 2

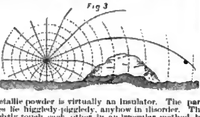


* Friday evening discourse delivered before the Royal Institution, June 4, 1897. We are indebted to London Engineer and L'Illustration for the engravings published herewith.

about 230 millions per second. The distance at which effects are produced with such rapid oscillations depends chiefly on the energy in the discharge that passes. A 6 in. spark coil has sufficed through 1, 2, 3, up to four miles, but for greater distances we have used a more powerful coil—one emitting sparks 20 in. long. It may also be pointed out that the distance increases with the diameter of the spheres, A and B, and it is nearly doubled by making the sphere solid instead of hollow.

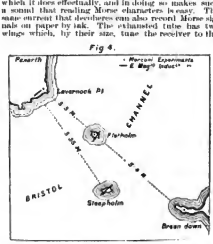
The Receiver.—Marconi's relay—see Fig. 2—consists of a small glass tube four centimeters long, into which two silver pole pieces are tightly fitted, separated from each other by about half a millimeter—a thin space which is filled up by a mixture of fine nickel and silver filings, mixed with a trace of mercury. The tube is exhausted to a vacuum of four millimeters and sealed. It forms part of a circuit containing a local cell and a sensitive telegraph relay. In its normal condition the

Fig 3



metallic powder is virtually an insulator. The particles lie higgledy-piggledy, anyhow in disorder. They lightly touch each other in an irregular method, but when electric waves fall upon them they are "polarized," order is installed. They are marshaled in serried ranks, they are subject to pressure; in fact, as Prof. Oliver Lodge expresses it, they "cohere"—electrical contact ensues, and a current passes. The electric resistance of Marconi's relay—that is, the resistance of the thin disk of loose powder—is practically infinite when it is in its normal or disordered condition. It is then, in fact, an insulator. This resistance drops sometimes to 5 ohms, when the absorption of the electric waves by it is intense. It therefore becomes a conductor. It may be that we have in the measurement of the variable resistance of this instrument a means of determining the intensity of the energy falling upon it. This variation is being investigated, both as regards the magnitude of the energy and the frequency of the incident waves. Now such electrical effects are well known. In 1866 Mr. S. A. Varley introduced a lightning protector constructed like the above tube, but made of boxwood and containing powdered carbon. It was fixed at a shunt to the instrument to be protected. It acted well, but was subject to this coherence, which rendered the cure more troublesome than the disease, and its use had to be abandoned. The same action is very common in granulated carbon microphones like Hunning's, and shaking has to be resorted to to decohere the carbon particles to their normal state. Mons. E. Branly—1890—showed that copper, aluminum, and iron filings behaved in the same way. Prof. Oliver Lodge, who has done more than any one else in England to illustrate and popularize the work of Hertz and his followers, has given the name "coherer" to this form of apparatus. He has much improved it. Marconi "decoheres" by making the local current very rapidly vibrate a small hammer head against the glass tube, which it does effectually, and in doing so makes such a sound that reading Morse characters is easy. The same current that decoheres can also record Morse signals on paper by ink. The exhausted tube has two wings which, by their size, tune the receiver to the

Fig 4.



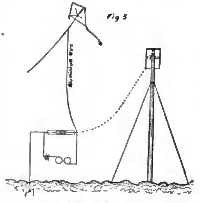
transmitter. Choking coils prevent the energy escaping. The analogy to Prof. Silvanus Thompson's wave apparatus is evident. Oscillations set up in the transmitter fall upon the receiver tuned in sympathy with it, coherence follows, currents are excited, and signals made.

In open clear spaces within sight of each other nothing more is wanted, but when obstacles intervene and great distances are in question, height is needed, tall masts, kites and balloons have been used. Excellent signals have been transmitted between Penarth and Brean Down, near Weston-super-Mare, across the Bristol Channel, a distance of nearly nine miles—Fig. 4. I must now show the system in operation. Mirrors also assist and intensify the effects. They were used in the earlier experiments, but they have been laid aside for the present, for they are not only expensive to make, but they occupy much time in manufacture.

It is curious that hills and apparent obstructions fail to obstruct. The reason is probably the fact that the lines of force escape these hills. When the ether is entangled in matter of different degrees of inductivity the lines are curved as, in fact, they are in light. Fig. 3 shows how a hill is virtually bridged over by these lines, and consequently some electric waves fall on the relay. Weather seems to have no influence; rain, fogs, snow, and wind avail nothing. The wings shown in Fig. 2 may be removed. One pole can be connected with earth, and the other extended up to the top of the mast, or fastened to a balloon by means of a wire. The wire and balloon covered with tin foil or kite becomes the wing. In this case one pole of the transmitter must also be connected with earth. This is shown by Fig. 5. There are some apparent anomalies that have developed themselves during the experiments. Mr. Marconi finds that his relay acts even when it is placed in a perfectly closed metallic box. This is the fact that has given rise to the rumor that he can blow up an ironclad ship. This might be true if he could plant his properly tuned receiver in the magazine of an enemy's ship. Many other funny things could be done if this were possible. I remember in my childhood that Capt. Warner blew up a ship at a great distance off Brighton. How this was done was never known, for his secret died shortly afterward with him. It certainly was not by means of Marconi's relay.

The distance to which signals have been sent is remarkable. On Salisbury Plain Mr. Marconi covered a distance of four miles. In the Bristol Channel this has been extended to over eight miles, and we have by no means reached the limit. It is interesting to read the surmises of others. Half a mile was the wildest dream.* It is easy to transmit many messages in any direction at the same time. It is only necessary to tune the transmitters and receivers to the same frequency or "note." I could show this here, but we are bothered by reflection from the walls. This does not happen in open space. There are a great many practical points connected with this system that require to be thrashed out in a practical manner before it can be placed on the

Fig 5



market, but enough has been done to prove its value and to show that for shipping and lighthouse purposes it will be a great and valuable acquisition.

* "Unfortunately, at present we cannot detect the electro-magnetic waves more than 100 ft. from their source."—Trowbridge, 1897, "What is Electricity?" page [illegible].

"I mention forty yards, because that was one of the first out-of-door experiments, but I should think that something more like half a mile was nearer the limit of sensibility. However, this is a rash statement, and at present verified."—Oliver Lodge, 1894, "The Work of Hertz," page 18.

PRACTICAL THOUGHTS ON DIET.

By J. HOBART EGBERT, A.M., M.D., Ph.D.

THE love of personal liberty, so patent in the human family, has long been a subject of comment, not only for philosophers, but for physiologists as well. To what extent one's desires may be accepted as proper guides in life is a question which constantly engages the attention of all those who labor for the promotion of public, as well as individual, welfare. Not a few—prominent among whom will be found the naturally strong and robust and the disheartened and desperate—are wont to disregard the higher organization of man—his vast personal liberty, bounded only by conscious reason—and to advocate that man's native tendencies will, like the unerring instinct of animals, direct him aright. Thus, Montesquieu expressed the sentiment of the multitude when he stated that the health purchased by a rigorous watching of the diet is but a tedious disease. But this belief, voiced by Montesquieu and reiterated by the liberty-loving masses, embodies a fallacy of no small magnitude or mean importance. When we consider the vast and direct influence of diet upon all the functions of life, when we reflect that man's education and not an inborn instinct directs him in the selection and proper use of food, and observe how invariably the penalty of abuse and transgression here, as elsewhere, sooner or later falls upon those who disregard the laws of Nature, we are led to know that to apply to diet—as to other habits of life—the principles of physiology and those allied sciences which reveal to us the laws governing the phenomena of Nature, is not to forfeit but to confirm, and by understanding their conditions to enlarge our liberty.

To those who would have as their only guide in dietetics a vigorous, and, doubtlessly perverted, appetite, we submit for careful consideration the following lines from the pen of England's profound physiologist and celebrated surgeon, Sir Henry Thompson. In a contribution to the Nineteenth Century this astute observer writes: "I have for some years past been compelled, by facts which are constantly coming before me, to accept the conclusion that more mischief in the form of actual disease, of impaired vigor, and of shortened life, accrues to civilized man, so far as I have observed in our own country and throughout Western and Central Europe, from erroneous habits in eating than from the habitual use of alcoholic drink, considerable as I know the evil of that to be. . . . I have come to the conclusion that a proportion amounting at least to more than one-half of the disease which embitters the middle and latter part of life among the middle and upper classes of the population is due to avoidable errors in diet. Further, while such disease renders so much of life for many disappointing, unhappy, and profitless, a term of painful endurance, for not a few it shortens life considerably."

The fact that many of the dietetic laws laid down by scientists have, when applied in actual life, been shown to be inadequate, is a stumbling block to many. The reason for this is not difficult of explanation, nor does it in any way lessen the value of the truth. In attempting to lay down hard and fast dietetic laws, pseudoscience has certainly evinced its incompetence by presuming to dictate laws to Nature rather than to expound existing truths; by confounding chemical with vital processes, and by disregarding the variations of force, organic strength, and particular requirements existing in different individuals and in the same individual under varying conditions of health, occupation, and environment. True science cannot be credited with such errors, for while its votaries may grossly err in their enunciations, the fundamental truths remain unchanged. Thus, through the pedantry of those who presume to interpret Nature's laws and formulate working codes applicable to life, the evils of ignorance and indiscretion are often thrust aside only to give place to the leaden tyranny of routine. What folly, as Herbert Spencer has observed, to suppose that the whole of dietetics lies in determining whether or not bread is more nutritive than potatoes, or in similar arguments. The physiologist of to-day is far wiser than the physiologist of yesterday, in that he recognizes in human intelligence a voice which speaks from within, and which evinces in mankind as in animals natural desires which require the cultivation and rational direction of education, rather than their overthrow and the substitution of purely artificial systems and habits of life.

Man's dietetic education begins in early childhood and continues throughout life. Some never receive other education in this direction than the example of others, while some, unsatisfied with strict adherence to an established precedent, by investigation, speculation and study enlarge the boundaries of their knowledge. Charles Lamb's "Dissertation on Roast Pig" fitly illustrates this theme and also points to the existence of what it now behooves us to consider more directly—to wit, a useful and natural appetite. To utterly ignore natural desires and maintain that judgment and education alone lead to the use of food suitable for the sustenance of the body would be to turn to the other and more irrational extreme. Charles Lamb's hero, in licking his burnt fingers—injured by handling the charred and heated remains of the litter—stirred up a latent appetite for roast pig and at once set about to appease it by devouring the still smoking carcass; and the train of incidents which followed the discovery of his violation of established rules show how, by a simple chain of natural circumstances, a rigid dogma may be overthrown. Yet who will argue that too much pork is not frequently eaten by many, or deny that educational training in things dietetic has not a direct influence upon the health and longevity of the Jewish people?

While there is a general correspondence in the kinds of food which the various members of the human family enjoy, there may also be observed in individuals a special inclination for certain articles of diet and a marked antipathy for others. Thus it is found that, to a normal appetite, distaste for any special article of food is often indicative of its inadaptation to the needs of that particular individual, while the craving for some questionable article of diet may be indicative of its value as a nutriment to the individual under the existing circumstances. In a word, appetite for food is often not only the expression of desire but of fitness as well. But, alas! it is not an invariable and unfailing guide to felicity. Does not the earliest record of human affairs contain an intimation of the perverseness of man's appetite—and that of woman as well—in the command to Adam: "But of the tree of the knowledge of good and evil thou shalt not eat of it; for in the day that thou eatest thereof thou shalt surely die." Nor does science give a perfect rule applicable to each and every case—for experience, and not theory, may alone reveal the truth. Not until we shall have gained a more definite knowledge of that subtile force which we term vitality—that force in virtue of which we exist—shall we be able to restrict with exact limitations the natural tendencies of erring man.

Admitting the function of our natural inclinations in respect to food, and granting that they indicate the existence of important relations between ourselves and our environment, which are revealed to us in no other way, it is not yet demonstrated that they are unerring guides in human life. It is physiologically shown, as well as philosophically emphasized, that with man the natural tendency of all carnal desires is to excess, and hence we can concede the fundamental government of nutrition to appetite only when appetite leads to the fulfilling of instinctive impulses by the legitimate and rational gratification of natural desires. In a word, man is called upon to employ both reason and knowledge in aiding and controlling his natural desires.

To be guided by nature implies not only that we must have natural tastes to gratify, but also that they are given due opportunity to indicate their normal preferences. By the habitual use of strongly seasoned dishes, of artificial flavors, of modes of cooking which conceal the natural taste of the substance, and even of a great variety of dishes at a meal, the appetite is daily perverted. The chief aim seems to be to please the palate rather than to satisfy the wholesome hunger of the stomach. It is true that the enjoyment of food exerts an influence in promoting the activity of digestive processes, but the relish must be real and not imaginary—general, not merely local—for the best diet gives not only temporary, but permanent and genuine satisfaction. "It is more than probable," says Dr. Hinton, "that some men lead languid and unenjoyable lives in the midst of every advantage, chiefly for want of some little article of food which nature needs, and which under a simpler regimen their tastes would decisively demand." Nor is this an extravagant idea, for there is ample proof that the importance of special portions of our food cannot be estimated merely by the value of their direct contribution to the system. The yeast is small in quantity, but it is all-important to the loaf. And there is every reason to believe that certain portions of our food act a part which may be compared to that of yeast in respect to bread. Nutrition is by no means a simple transference of so much matter into the body, but a long series of changes, in which certain elements are subservient to others. The repair of the

substance of the body by one part of the food is dependent upon forces derived from the changes which other parts undergo. No mere quantity, though ample, and every portion unexceptionable in its way, will give the true result, unless there is also present the complementary substance in due proportion to supply the needful stimulus.

To those who maintain a certain simplicity of living, who avoid the use of stimulants and narcotics, and obey the laws of health regarding exercise, fresh air, sleep, cleanliness, and general habit, great license may be allowed in matters of diet. But do such persons constitute the masses? Again, no matter how healthy a child, or how physically strong a man he may be, we know that they are incompetent to select proper food for the nourishment of their bodies. Does this emphasize the value of instinct or of reason and education?

One thought in conclusion. What effect did a knowledge of the methods and habits of civilized men have upon the North American Indians? They easily learned the vices and excesses of civilization without comprehending the laws necessary to the maintenance not only of that civilization but of life itself under the artificial conditions which it produces, and the result is, or at least soon will be, seen in the extinction of the race.—Dietetic and Hygienic Gazette.

APPARATUS FOR ROENTGEN WORK.*

OWING to the interest aroused by Prof. Roentgen's discovery, a few words on the construction of induction coils and other pieces of apparatus in connection with the production of the X rays may not be out of place. Any person with an ordinary amount of ingenuity and some little mechanical skill can make the apparatus mentioned below, and much cheaper than it can be bought.

The first and perhaps most important point is the generation of the necessary power requisite to run the coil; this can be obtained from primary batteries, secondary batteries or accumulators, and the ordinary supply mains. Of primary batteries the most powerful is the bichromate, composed of a plate of zinc and two plates of carbon in a saturated solution of bichromate, to which is added strong sulphuric acid. This, unfortunately, has the disadvantage of falling off in strength after some time. Daniell's cell, composed of a cylinder of copper surrounded by copper sulphate, and a zinc plate in a porous pot and surrounded by zinc sulphate, is more constant, but not so powerful. Secondary batteries have the disadvantage of having to be recharged, and this can only be done at a dynamo or off the supply mains; otherwise this is a very convenient and portable form for producing the current. These must be bought, as the manufacture is of great difficulty and involves the use of large currents in the formation of the plates. The coil can also be driven off the supply mains, great care being taken to have sufficient resistance in circuit to prevent too large a current flowing through the primary and fusing the wire, and may be, the leads of the house. An alternating current can be used and slightly simplifies the construction of the coil, but an ordinary resistance cannot be used in this case. It has been shown that these results can be produced with short exposures by a coil giving a spark of about 6 inches, and the production of this I propose to describe.

The coil, as represented in Fig. 1, is composed of a bundle of iron wire, surrounded by two layers of

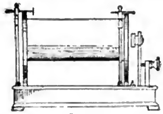


FIG. 1.

thicker wire, called the primary, which carries the inducing current; and this is again surrounded by a large number of coils of very thin wire, called the secondary, in which the high pressure is produced; a contact breaker, and a condenser. The iron core is composed of well annealed iron wire, of No. 30 B. W. G. (Birmingham wire gauge), 28 Am. W. G., made into a bundle 14½ inches by 1½ inches, made red hot in a fire and allowed to cool slowly. When cold, the whole bundle, kept together by wires round the outside, is soaked in shellac varnish or melted paraffin wax until it has penetrated right through. This is to prevent destructive currents being set up in the iron. When dry a layer of brown paper, soaked in paraffin wax, is placed round; and over the whole a thin ebonite tube. On this is wound the primary wire, composed of two layers of No. 14 B. W. G. (12 Am. W. G.) cotton covered and well soaked in paraffin wax. About two pounds of wire will be required. A layer is wound on, leaving ends long enough for making the connections, and over this a layer of paraffined brown paper, then the other layer of wire, finishing at the end at which the winding started. The primary wire will safely carry eight amperes without heating appreciably, and very likely ten could be used. Over the last layer is placed a layer of paraffined paper, and then a thin ebonite tube. On this is wound the secondary coil, which is best composed in sections—in this coil, eight. This arrangement, by placing wires having a great difference of potential away from one another, much diminishes the chance of internal sparking and thus ruining the coil. The wire is No. 36 B. W. G., 38 Am. W. G., of which twelve pounds will be required, silk covered, and the bobbins containing the wire should be soaked in paraffin wax before winding. A pound and a half of wire is wound upon each section, a former being made corresponding to a section and having one side removable, and may be driven from an ordinary sewing machine table. Fig. 2 will show the method of winding.

* By E. A. Holmes, in the Photogram.

The wire is drawn through a hole near the lower part of the former, leaving enough projecting for connections, and the bobbin filled with wire, 1½ pounds. The next is wound in the same way, and the coil turned round before placing upon the core, thus, in two adjacent sections the wires run in opposite directions, as will be seen from Fig. 2; the two inner ends are

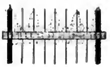

FIG. 2.

connected. The third coil is wound and placed like the first, the outer end being joined over the top of the division, with the outer end of the second coil. The fourth is like the second, and has its inner end joined to the inner end of the third, and so on, the eighth coil having one end free and is one of the terminals, the first coil being the other. The coils should be soaked in paraffin wax; the divisions may be thin ebonite of one-sixteenth to one-eighth inch thick, or of two or three thicknesses of celluloid, such as is used for the thick films, which I find very useful for this purpose. The ends may be made of ebonite or well seasoned mahogany about ⅜ inch thick. Of course there is no connection between the primary and secondary. If there is, the coil is of absolutely no use. The soldering of joints between the coils should preferably be done with resin, as "killed" acid may corrode the wire and cause heating, and perhaps melting of the wire. The outside should be covered with thin sheet ebonite bent round. This prevents sparking on to the coil. The secondary terminals should be supported, about eight inches apart, on glass rods. The coil, if it is to be used with continuous currents, must have some method of making and breaking the current. The contact breaker may be composed as in Fig. 3.

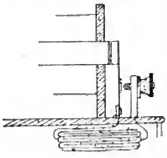

FIG. 3.

A small iron hammer, 1¼ inches in diameter, supported upon a spring of brass having a screw touching against it. The points of contact should be platinum, to guard against corrosion. The hammer is opposite the end of the iron core and works thus—the current comes from the battery through the screw and spring to the primary coil and back to the battery. This makes the iron core a magnet, which attracts the soft iron hammer, dragging the spring away from the point of the screw. This breaks the current, the core ceases to be a magnet, no longer attracts the hammer, and spring flies back again, making contact. Another form of contact breaker is that shown in Fig. 4.

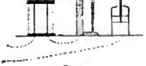

FIG. 4.

A rod is pivoted in the center, at one end of which is a platinum point dipping into mercury, on the other is a soft iron armature, below which is an electro magnet. The current from the battery flows to the mercury up the platinum point, along the rod, down the support, and round the magnet wire, through the primary, and back to the battery. This excites the magnet which attracts the armature, raising the point out of the mercury, breaking contact, current ceases and the spring pulls the rod down, again making contact. The mercury is covered with a layer of paraffin oil, to prevent sparking and also oxidation of the surface. For large coils the last named is the best, being more under control. For continuous currents a condenser is required, and is for the purpose of receiving the current induced in the primary on the break of the current by the contact breaker, which would otherwise leap across the gap between contact breaker and platinum point. The charge stored up in the condenser also assists the current in the primary wire on the make of the current. It is composed of 200 sheets of tinfoil, 9 inches by 9, having a layer of good paraffined paper between of slightly larger size than the tinfoil, the corners of alternate sheets being joined together, and each set being joined to the contact breaker as in Fig. 3, which shows the condenser in position; the condenser should, when finished, be placed under heavy pressure until the paraffin wax has set. It is most important that no connection exists between the two sets of tinfoil sheets, as this would short circuit the contact breaker and no effect would be produced upon the coil. The end of the primary should be joined to the foot of the spring in the first kind, and to the magnets in the second kind of contact breaker, the screw in the first and the mercury in the second being joined by a No. 14 B. W. G. (12 Am. W. G.) wire to a large terminal. The other end of the primary is joined to a like terminal, placed about two inches away. The wire on the magnets of Fig. 4 must be the same as the primary wire. The secondary terminals should be placed as far away as possible from the primary terminal and contact breaker, as a spark from an induction coil such as this would be very dangerous, if not fatal to some people. Sparks should not be taken to the body when above ½ inch in length. If the current be taken from the lighting mains a variable resistance must be placed in series with the primary; enough to bring the current down to about six amperes, this being quite enough to run the coil. As this depends upon the size of the house leads, the advice of a competent electrician should be taken before attempting, or the mains may easily get fused, owing to the resistance of the primary being very small, about half ohm. If an alternating circuit be used for lighting, an ordinary resistance cannot be used, but a device known as a "choking" coil is used. This is a coil of thick wire, containing an iron core, which can be moved in or out, the farther the core is in the less the current; but, as above, advice should be taken before meddling with any electric lighting mains. A "choking" coil requires adjusting for every circuit. In the last case the condenser and contact breaker are not required, the oscillations of the alternating current having the same effect. If high frequency and potential be required, and very small current, the following device may be adopted.

One terminal of the secondary is connected to the inner coating of three half gallon Leyden jars, the outer coatings being connected to earth. The inner coatings of the jars are connected to a gap between two highly polished brass balls of an inch in diameter and about a quarter of an inch apart; the other side is connected to a coil of well insulated wire (about one pound of No. 32 B. W. G., 31 Am. W. G.) wound on an ebonite tube and well soaked in paraffin wax, the other terminal of the coil is connected to three Leyden jars, as in the first case, but with no spark gap being connected directly to the other end of the coil. Another coil of wire is wound over the first, being well insulated from it. A very high frequency of alternation is produced in the last coil, providing a continual discharge takes place across the gap (see Fig. 5). All the effects produced by

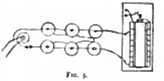

FIG. 5.

Tesla before the Institute of Electrical Engineers can be produced, on a smaller scale, of course, by the above apparatus; and it has been said the X rays are produced most readily by these means. An ordinary incandescent lamp globe, of which the filament is broken, can be used for all the above mentioned Tesla effects, but is usually not highly rarefied enough to produce Prof. Roentgen's X rays. The tubes required for this work are those first produced by Crookes, and used by him for studying his radiant matter (see Electrician, January 16, 23 and 30, 1891), and are glass bulbs having an exceeding high vacuum, much higher than the ordinary "vacuum," or Geissler tube, which is of no use for this work—at all events, without exceedingly long exposures. The connections with the interior are made by means of platinum wire fused into the glass, this metal being the only one which has about the same coefficient of expansion as glass. These electrodes, as they are called, end in the pattern of tube most used in England, in a ring of aluminum and a disk of the same metal, respectively. (See Fig. 6.) The bulb is pear-

FIG. 6.

FIG. 7.

shaped, the disk suspended from the smaller end and the ring projecting from the side about three-quarters of an inch below the disk. Disk and ring are of about one inch in diameter. The generally used Continental form (which is also made in England) has no ring, only a wire projecting from the side, the disk being nearer the top of the tube. (Fig. 7.) The discharge is of a pale violet, the glass of the tube fluoresces an "apple green" tint.* The high vacuum in these tubes is obtained by means of a mercury pump, of which the Toepler is a good form, which I will describe (see Fig. 9). The diagram shows one form of the Toepler pump. In the other, the long tube, d, is replaced by a mercury valve, thus doing away with the liability of fracture of the long tube. The tube, a, has a bulb, b, of comparatively large capacity, blown at the upper end. Out of the upper end of this runs the tube, c, from which the

* The form of tube finally adopted by Prof. Roentgen himself is shown in annexed sketch, Fig. 8. It is being made by Baird & Tatlock, Cross Street, Hatton Garden, E. C., to whom we are indebted for the use of the first example made, from which to make our sketch.

air is discharged. The air enters from the tube to be exhausted by the tube, d, on to the end of which it is fastened either by fusion of the glass or else by an air-tight joint of rubber. The tube, a, is about 40 inches long to the bulb; c is about 36 inches from the level of the top of bulb; d is about 30 inches high. The reservoir, e, containing mercury is connected to the lower part of a, by means of a flexible rubber tube, and is long enough to be raised above the bulb, and contains enough mercury to fill the bulb and tube, a. The operations are: The reservoir is raised to fill the bulb, b,

FIG. 1.

the tube is fastened on the end of d, c dipping below mercury. The reservoir is now lowered, the air rushes into b, from the tube being exhausted. The mercury has risen in c, by the pressure of the atmosphere. The reservoir is again raised, cutting off d, and forcing air out before it through c; the operation is again repeated, always driving all the air out of c, by allowing a small quantity of mercury to flow over from the bulb. If very high vacua are required, the tube to be exhausted is filled with carbon dioxide and exhausted, the residual gas being absorbed by a tube containing caustic potash being placed between the tube and a, the bulb is sealed off by a blowpipe flame before withdrawal from the pump. The extent of the vacuum can be judged approximately by the tube, c. When this stands at the barometric height, generally about 3 inches, when the reservoir is in the position of the sketch, the vacuum is fairly high. Gas is absorbed by the aluminum electrodes, is gradually given out, and will impair the completeness of the early obtained vacuum. This can be got rid of by heating the partly exhausted tube, and if an induction coil be joined to the electrodes, the extent of the vacuum can be gaged from the discharge produced in the tube. The tubes are beyond the scope of any one except an experienced glass blower, and the exhaustion is very difficult, and they are, therefore, better obtained from a manufacturer. The exhaustion generally takes a large amount of time.

To return to our coil. It may be mounted upon an ebonite or mahogany base containing a cavity in which the condenser is placed. The frequency of the dis-

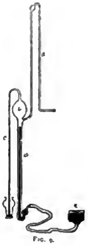

FIG. 2.

charge may be increased by tightening the screw of the contact breaker, the greatest being obtained when it is giving the highest note. If a smaller coil be required, say a two inch spark, the core should be composed of iron wire (No. 30 B.W.G., 28 Am. W. G.) treated as described above, about ten by one inches, the primary wire two layers of No. 16 B. W. G., 14 Am. W. G., double cotton covered and insulated as described above; the secondary is composed of four pounds of No. 38 B. W. G., 40 Am. W. G., wound in sections, double silk covered. A hammer contact breaker should be used for such a small coil as this. The condenser should be about 100 sheets of tinfoil, nine by seven inches.

The wire is, of course, the most expensive article, and should be obtained direct from the manufacturers. The paraffin wax can be obtained from the dealers in electrical goods. It should not be heated too high, as this slightly destroys the insulating power; it is best heated in a water bath, as paraffin wax melts at about 100 F. The weight of the six inch coil will be about twenty pounds. Shellac varnish can be used for insulating purposes, and the glass pillars of the secondary terminals should be coated with it inside and out if tube be used. Thin wires only are needed for connections to the secondary coil, as the current flowing is exceedingly small, the potential being very high.

The Leyden jars can be made of half gallon glass jars, the glass not too thick and as white as possible, coated inside and out with tinfoil pasted on to about four inches from the top, the bare glass being coated with shellac.

A new imitation gold has been prepared by Theodor Held, Menien, Germany. It is an alloy of copper and antimony in the proportion of 100 : 6, and is prepared by mixing the antimony with the molten copper at a certain temperature. The antimony is previously cast in gold. By these precautions a malleable metal is obtained, instead of, as usual, a porous substance. The alloy has a high tenacity, and is, in fact, harder than gold itself. When finished it cannot be distinguished from the precious metal at sight, even by experts.—Uhland's Wochenschrift.

ON THE EFFECT OF MUSIC ON CAGED ANIMALS.*

By FRANK COLLINS BAKER.

SOME time ago the writer was induced to experiment upon the animals in the Zoological Garden in Lincoln Park, with respect to the effect of music upon them, and the result may be of some interest to others working on psychological lines. The experiments were made at 6 o'clock P. M., two hours after feeding, and the instrument used was a violin.

Felis concolor Linné. Puma Panther. When the music first began, two specimens of this species were resting in the back of the cage half asleep. At the first sound of the violin they started up, and could not for a time locate the sound, the writer being some distance from the cage. They showed, however, that they liked the sound, and when the player came as close as he could to the cage, they manifested their appreciation by lying down at full length and placing their heads between their paws. During this time the music had been of slow and sweet pieces, such as "Home, Sweet Home," "Annie Laurie," etc., etc. Suddenly, the player changed "Home, Sweet Home," to the "Irish Washerwoman." At this change the panthers worked their tails nervously, and twitched their ears, and as it was kept up for a time, they got up and began pacing up and down the cage. From this action the writer judged that either the jig music, being sharp and piercing, hurt their ears, or that it was distasteful. After playing several jigs of this kind the player again relapsed into soft strains, when the animals slowly settled down in their old positions.

Felis onca Linné. Jaguar. This animal behaved much as did the panthers. While the jigs were being played he acted in a very nervous manner, jumping from a shelf to the floor of the cage and back again. Soft music seemed to quiet him. As the writer was leaving the jaguar's cage, having ceased playing for the time being, the animal walked up to the corner and reached out with his paw toward the player as far as he could. Whether this action was intended to call the player back or was simply done to catch hold of him, as many animals will do if a person gets too near to the cage, the writer cannot say. It was a curious fact that when the paw was extended the claws were all retracted.

Felis leopardus Linné. Leopard. Two specimens of this species did not seem to notice the music to any extent, except at first, as a matter of curiosity.

Felis leo Linné. Lion. The lioness Juno, with her three cubs, occupied a large cage, and the player's attention was next directed to these. While the music was being played to the other animals the lioness and cubs had been listening and watching, the cubs playing about their mother's haunches. As the violinist drew near the cage the cubs scampered behind their parent, the latter greeting the player with a gentle hiss. As the music struck up a lively jig the cubs stood upon their hind legs and peeped at the player over her haunches. They appeared very curious and much puzzled, hearing these sounds for the first time. Desiring to test their appreciation, the player slowly backed away from the cage, playing all the time; as he retreated, the cubs gradually came to the front of the cage, and the mother crawled to the front and placed her two forepaws between the bars and stuck her nose through as far as she could. After retiring to the side of the hall the player again moved toward the cage, but the family did not move, nor evidence any displeasure when he came very close to them; in fact, so close that he almost touched the great paws of the lioness. As he played the soft strains of "Home, Sweet Home," the cubs and mother sat motionless, in rapt attention, the former turning their heads from side to side. A jig played very rapidly caused the cubs to prance about in a lively manner.

Felis tigris Buff. Bengal Tiger. The music had a peculiar effect on the pair of animals in this cage. The male paid absolutely no attention to it, save glancing in the direction of the player and giving a vicious snarl. The female, however, acted as though she liked it, for she jumped upon a shelf and placed her paws and nose through the bars as described under the last species. A second experiment with the male, later, when he was stretched out upon the floor of the cage, caused him simply to look at the player, twitch his ears, and viciously spit and snarl at him. The female, however, on all occasions showed that music was not distasteful to her, and that it was, on the whole, pleasing.

Hyena vulgaris Buff. Hyena. This animal is probably the most cowardly of all the mammals, and the only effect which music had upon two individuals was to cause them to retreat to the farther end of the cage and try to squeeze out between the bars. A lively jig frightened them nearly to death, and made them tremble in every limb. Strange to say, however, they did not howl or make the least noise.

Quadrumana. The Monkeys. (Genus Cynocephalus.) The monkeys evidenced great curiosity at the music, but did not seem to show either pleasure or displeasure at the sounds. A South American sooty mangabey, however, seemed to be rather pleased with the strains, particularly the jigs. This animal is of a quarrelsome disposition, and is, therefore, kept separate from the other monkeys. It was thought by Mr. Sweeney, the keeper, that the sounds might awaken a feeling of anger in him, but such was not the case. As the violinist drew away, he followed as far as his cage would allow. A spark of reason was observed in this animal. His cage is of glass all around, and in order to hear the music better he placed his ear to a crack in the door. This he did several times as the player drew near or went farther from the cage. The monkeys confined in the larger cage, also of glass, formed themselves in a broken semicircle about that part of the cage nearest the violinist, and looked at him in apparent wonder. As he moved away from them, they arose from their sitting posture with one accord and followed him along the side of the cage. This was probably simply curiosity, although the music may have given them some pleasurable sensations. On the whole, the monkeys did not show as much intelligence as might have been expected from their high position in the scale of nature.

Pelecanus fuscus Linné and P. erythrorhynchus Gm. Brown and White Pelicans. The pen containing these birds is situated next to the monkey cage, and the music was next tried upon them. The effect was somewhat startling, for they all began to jump about, flap their wings, and snap their huge beaks; this might, perhaps, be called dancing. When the violinist drew near the cage, they snapped at him with their beaks.

The other birds in the animal house paid very little attention to the music, partly, perhaps, because they were sleepy. Several varieties of parrots, herons and smaller birds were tried in turn, but without producing any results worthy of mention.

Canis latrans Say. Coyote. The last experiment tried was upon a den of coyotes in the park. When the playing began all the animals were in their holes, but the first note had hardly been struck when they came running out, and raced up and down their den until they had located the sounds. When this was done they all squatted in a semicircle about the violinist, he having approached the bars of the den as near as possible, and sat in silence listening to the music. When it ceased they ran up to the player and pawed at him through the bars, indicating as plainly as possible that they wished to hear more. When he began to play again they again silently formed in a semicircle. This experiment was tried a number of times, but always with the same result. During this time not a sound was uttered by the coyotes, but a wolf in the den adjoining howled lustily. Here, as in the other cases, soft, sweet music seemed to be better appreciated than loud, harsh music.

Besides music made up of regular pieces, all sorts of sounds were made by the violinist—screeches, piercing notes, imitations of a cat, cow, rooster crowing and pig squealing, but these did not seem to have much effect. The loud, harsh and piercing notes seemed to affect their ears, for they moved them about nervously as though the noise hurt the sensitive nerves. To sum up general impressions, slow and soft music was received, as a rule, with more signs of pleasure than the lively jigs. The females, also, seemed to pay more attention to the music, and to be more pleased with it, than were the males. The nocturnal mammals were more interested than were the diurnal birds. This was probably due to the fact that the experiment was tried after dark, when the animal house was lighted only by electricity. It was a curious and interesting fact that the whole performance was conducted without any noise other than an occasional grunt from the lions. The experiment is worthy of repetition, and should be made at different times during the day, as in the early morning and at noon, just before and after feeding, etc., to see whether or not these conditions have any effect upon the result. The writer is convinced that many interesting and valuable facts may be learned by experiments of this character.

SPINNING POWERS OF CERTAIN EGGS.

IT is well known that the protoplasm of many one-celled animals may flow out as excessively delicate threads of living matter that exhibit remarkable currents and contractile phenomena. Something similar to these fine "pseudopodia" is met with in certain cells of many-celled animals, as in the pigment cells of the retina, etc. In a recent paper by Gwendolen Foulke Andrews* it is claimed that the eggs of starfish and sea urchins form very much the same sort of delicate pseudopodial filaments as are produced in those one-celled animals.

These threadlike processes are "spun" out from the protoplasm of the egg in such exceedingly delicate filaments that they have escaped notice and have now been revealed only with good lenses and exceptional optic resources.

From the elevation of the egg's surface that meets the sperm a "tuft" of fine threads is spun out; the whole surface of the egg spins out fine threads to make the egg membrane; the egg spins during cleavage; it spins out the cilia that move the blastula; it spins filaments across the cleavage cavity and from one germ layer to another in the gastrula; and the polar bodies spin like the rest of the egg.

These threads spun out are flowing material that branches, anastomoses, shows currents and other phenomena very much as do the pseudopodial filaments of such one celled animals as Gromia.

The membrane that is formed after entrance of a sperm is made in the sea urchin by the following spinning phenomena. In normal eggs of Echinus clear, homogeneous, straight, smooth filaments flow out from the egg, very close together, and all attain the same length about the same time. These filaments then seem to fuse at the tips to make a ceilinglike film that grows thicker. The space between the filaments is then filled in—in some undetermined way—and thus the membrane is completed.

In abnormal eggs the spinning is irregular and more in the form of tufts and brushes that are more readily observed.

In the starfish after such a membrane is formed the egg sends out a tuft of threads from the place where the polar bodies were formed and then ceases to spin; soon the general surface spins again, and continues to do so during cleavage. These filaments branch and anastomose; they may bend suddenly at the base and even bend over at right angles at some point in their course; they may start from the surface of the egg at various angles, even tangentially; they may run out and attach themselves to the egg membrane.

When cleavage of the egg begins the spinnings show peculiar activity near the plane where the cells will separate. As the cleavage furrow is formed, threads spin from one side to the other, so that the two cells are connected by cross filaments as fast as they are separated by the plane of cleavage. The liquid between the cells is crossed by many most delicate strands and skeins of filaments that connect the two cells.

When the two cells subsequently approach and flatten against one another, the connecting strands shorten and thicken as if contracting to draw the cells together. When pressure is applied to such cells, the connecting threads appear as if resisting separation of the cells and as if more active in drawing them together.

Later, when more cells are formed, the same pheno-

*Journal of Morphology, February, 1897, pp. 267, 280.

mena are seen, and when the cleavage cavity is present it is crossed by a network of interlaced filaments spun out from the inner ends of the cells. These filaments connect adjacent cells and also the most remote cells of the blastula.

When the blastula is ready to swim, the external spinnings cease for awhile and then start again as numerous processes from the general pellicle, all becoming very long and active as the well known "cilia" that propel the blastula through the water.

In the gastrula stage both entoderm cells and ectoderm cells spin filaments that cross the blastocœle and connect all the cells. When the mesenchyme cells are formed they, too, spin many filaments that connect with the other cells and with other filaments, so that the blastocœle is traversed by a very complex network of anastomosing filaments arising from all the germ layers. These internal spinnings remain active up to the time of formation of the proctodeum, at least.

The polar bodies spin, from the first, very fine pseudopodial filaments that soon unite with the egg and with the egg membrane, as well as with filaments from the egg, so that the polar bodies are henceforth (up to the period of the late gastrula, at least) united to the egg, and to the resulting cells, by threads of living material.

The shape of the polar bodies may be changed as distorted by contraction of these filaments; and change of place of the polar bodies seems also to be due, at times, to contraction of the filaments.

In the anastomosing network that connects the egg with the polar bodies material is carried hither and thither in the currents that flow along the threads.

Eventually the polar bodies may be taken in to the blastula, through the cleavage pore, and henceforth be connected with the network spun out from the inner ends of the blastula cells and, later, with the filaments from the entoderm cells of the gastrula also.

The natural criticism that these spinning phenomena are abnormal, pathological, and hence of less wide interest, is met by the author with the statement that every precaution was taken to maintain normal conditions, and that the eggs described were from lots that formed normal larvæ, or even themselves grew into normal larvæ after the observations. Moreover, it is granted that heat, polyspermy, immaturity of the egg and adverse states of the water resulted in very profuse spinning phenomena; but these truly pathological phenomena were very different in character and easily distinguished from the less obvious phenomena believed to be undoubtedly normal.

It is thus claimed that in these normal Echinoderm eggs the protoplasm can project delicate living filaments. That these are concerned in the formation of the egg membrane. That they connect the cells during cleavage and gastrulation, so that the protoplasm is continuous throughout the larva and not separated by the cell walls.

As appearances indicate that these connecting filaments are contractile and that they aid in drawing the cells together, they may thus prove to be the basis of the so-called "cyto-tropic" movements exhibited by the blastomeres of various eggs.

Moreover, as these filaments are living bands and as material passes along them from one cell to another, the author thinks they may prove to be the means of that co-ordinating communication in the cell aggregate postulated by certain workers in the field of experimental embryology.

The polar bodies are said to spin like the cells of the egg for a long time after their formation and to remain so long in protoplasmic continuity with the other cells that there is a possibility they may not be entirely without a place in the developmental changes.

The peculiar activities of the protoplasm of these eggs, together with many general questions connected with such phenomena, will be considered in a second paper, now in press.

Though these remarkable phenomena are new to our knowledge of eggs, the reviewer would suggest that what is here seen as living filaments may have appeared to other observers as a protoplasmic envelope on the outside of the egg. Thus it may be that the very thick covering "Protoplasma mantel" figured and described by Selenka* in the Ophiurid Ophioglypha lacertosa and the much thinner "Protoplasma schicht" in the Echinid Strongylocentrotus lividus, which also enters the cleavage cavity, are really a collection of spinnings, possibly somewhat pathological. In the last named case this outer envelope of the egg has recently been emphasized by Hammar† as a connection between the cells.—The American Naturalist.

ELECTRICAL TREATMENT OF PHYLLOXERA.

VARIOUS methods have been tried for making life unpleasant for the phylloxera and saving the vineyards, which else appeared doomed, says the English Electrical Engineer. One promising method, extremely unpleasant to others as well as the phylloxera, involved the extensive application of carbon disulphide. According to L'Elettricità, in Italy, or, at any rate, in the island of Elba, they have tried electricity. The inventor, who has the un-Italian and Teutonic-looking name of Furin, has established at Porto Ferrajo a method of killing the phylloxera on the vine by puncturing the stem with a needle, and sending a current down to the roots. The operation has to be repeated about three years in succession, and is said to cost under 50s. per acre. The action of the current is ascribed to the production of ozone, and the vitality of the plant is said to be in no way impaired by the treatment. There are no details as to voltage or current used, and it may also be added that L'Elettricien some months ago stated that experiments recently made by an engineer of the Siemens & Halske Company to destroy the phylloxera on vines, by means of ozone generated by electricity, had given unfavorable results.

According to Austro-Hungarian patent law, patents may be taken from their holders for an appropriate compensation, if it be in the interest of the army, government or the public.—Stahl und Eisen.

SINGLE RAIL RAILWAYS—THE BEHR SYSTEM.

THE main feature of the Brussels International Exhibition, now in progress, is the Behr monorail railway, on which Mr. Behr is said to have expended $150,000, and by which he expects to demonstrate that the system is the one best adapted to maximum speeds. For our illustrations and the accompanying details we are indebted to Engineering.

There is, of course, nothing new in the idea of a single rail railway. Long before Lartigue's time it had been put in ineffectual practice. As long ago as 1826 the notion found favor, was tried and abandoned, to be taken up again and again uselessly. Of late years the most elaborate experiment was the Meigs elevated single line railroad, built at Boston, and tested to absolute discredit. There have been but two systems, of modest application but of undoubted value, on these lines of invention. These were the Lartigue monorail railway and the Caillet system.

Charles Lartigue's invention was an admirable one for its special purpose. He was the engineer to a French company in the large agricultural interests in Algeria. Decauville lines were laid down over the company's estates, but they proved a failure, on account of sand storms that buried the permanent way, obliterating the track often in a few hours. On this account Charles Lartigue built his lines on trestle work, with a single rail, and made his wagons pannierwise; by this means he surmounted the difficulty of the sand storms, and was able to haul his crops without interruption, by mules. With the hopefulness of the inventor, he believed that what was well adapted for an Algerian desert should find a wider application, and he exhibited his elevated railway with a modified construction at an exhibition held at Rouen, about 1883. Again, it appeared in Paris, in 1884, at an agricultural show, for M. Lartigue's ideas of the usefulness of his system did not appear to go farther than its application to agricultural purposes. The line at the Paris show was only a few hundred yards in length, but it was an exhibit of special interest, for the train of cars was propelled by electricity, the current and motors having been furnished by Messrs. Siemens. It was the prototype of the present experiment at Brussels, but it found no practical adoption.

During the following year Mr. F. B. Behr, of 6 Old Jewry, became interested in the Lartigue railway, and sought a wider field for its application. He built the experimental line at Westminster in 1886, and did not convince the public, nor possibly himself, that the system could be profitably applied to ordinary railways. Still, his experiment led to practical results. In 1888 he completed a passenger and freight line from Listowel to Ballybunion, a distance of 10 miles; and this line is still in profitable operation, though, of course, on a small scale, with light traffic, except during the tourist season, when it is busy enough. In France there is another railway—a state railway—about 12 miles long, from Feurs to Panissières, a minor branch of the Paris-Lyons-and-Mediterranean Railway. In other parts of the world—in Russia, in Trinidad, Guatemala, and elsewhere in South America—there are some 15 or 20 of these lines in successful working, none of important length, and nearly all used for hauling ore, the system being found well adapted for this purpose, where difficult localities involving sharp curves render the use of aerial railways impracticable. At a Spanish mine in the Pyrenees one of these railways is worked electrically.

None of these insignificant applications of the system has anything in common with the latest development, and until now it has never been pretended that the monorail system could secure higher speed, greater safety, and more comfort to passengers than the ordinary railway. But the history we have so briefly sketched is interesting, as linking together the little sand-swept tramway in Algeria with the bold experiment of Mr. Behr at Tervuren.

THE BEHR SINGLE RAIL RAILWAY—INTERIOR OF CAR.

The monorail exhibit consists of three parts, not counting the various objects shown to illustrate the early history of the system. These are the permanent way, the carriage, and the power station. The length of the line is about three miles, and consists of two parallel straight portions connected by curves at each end of about 1,600 ft. radius; these arcs of circles are joined to the straight lengths by transition curves. The line is not level throughout, one-half the distance, including a part of the curves, being laid with a grade of 1 in 100. The great ring fence inclosing this ellipse does not lie within the limits of the Tervuren Park, but extends from one end of it, so that the entrance to the exhibit is situated on the boundary of the park.

While Mr. Behr limits his estimate of speed to something less than one hundred miles an hour, he will conduct a series of experiments to ascertain the maximum rate attainable. It may be added that his experiment is being watched with much interest by the Belgian Corps des Ponts et Chaussées, and a report by state engineers will be prepared at the end of the exhibition.

The railway being continuous, and there being only one vehicle placed on it, there is no need for sidings, or for any switches or their equivalent, but devices for effecting junctions form a subsidiary part of the exhibit. The carrying rail is placed on the top of a triangular trestlework of steel, strongly braced in all directions, and resting on steel crossbearers laid in the ballast. Besides the single top rail, there are attached on each side of the trestlework two rails of a special section, and laid flat with the heads outward. These serve as guide rails, on which several series of small inclined wheels mounted on the carriage take a variable bearing as the train is in motion. The triangular members of the trestle are about 4 ft. high, the distance from the top of the sleeper to the bearing surface of the rail being 1·250 meters. The standards are placed at distances of 1 meter (39 in.) apart, except at rail joints, where the distance is made one-half. The carrying rail is of ordinary section, and 82 lb. to the yard. The conductor is attached to the sleepers, and is supported on insulators secured to the sleeper by stud bolts, the conductor rail being held by two screws provided with spring washers. Copper strips form the connections between the conductor lengths.

The carriage is provided with pointed ends to diminish the air resistance, and the inclined faces forming the ends are fitted with adjustable vertical louver plates which can be opened with the view of utilizing them as air brakes. The compartments inclosed within these pointed ends are occupied by the driver and conductor of the car respectively. The vehicle has a sitting capacity for one hundred passengers, arranged in four rows, two on each side of the carrying rail. There are two electric motors to each truck, making four in all. These are placed in the lower part of the carriage body below the seats. The bottom of the car extends to within a few inches of the sleepers, and is incased throughout. Within this space is a large amount of mechanism, including the sets of lateral wheels that bear against the side guiding rails. The two trucks, of four wheels each, running on the main rail, are within the recess formed by the framing of the seats. The weight of the carriage in running order is about fifty-five tons. The vehicle is 58 ft. long and about 11 ft. wide. It is framed entirely of steel. Its bottom edge is 7 in. clear of the sleepers, and the floor level is about 5 ft. above, the height of the bearing rail from the sleepers being 4 ft. 1⅛ in. From the floor or upper deck of the carriage the sides rise so as to give a lofty inclosure for the passengers, and the roof is arched. The carriage is made with a deep recess running for its whole length to receive the wheels and trucks on which it is carried. The driving and guiding mechanism is contained in the hold of the carriage, the electric motors being attached to the framing of the lower deck. Internally the carriage is divided into compartments, one of which, 20 ft. long by 5 ft. 6 in. wide, being reserved for the use of royalty. No expense has been spared in the luxurious internal fittings of the compartments, which are upholstered in Utrecht velvet, the joiner's work being

THE BEHR SINGLE RAIL RAILWAY—EXTERIOR OF CAR.

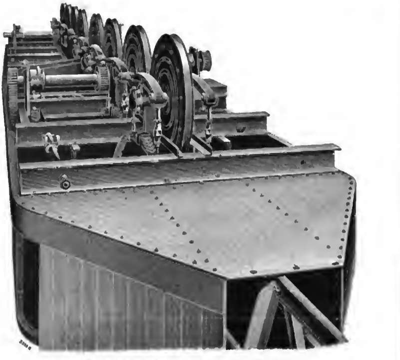
in Spanish mahogany, and the roof linings of imitation leather. The weight of the carriage is about fifty-five tons, which is considerably in excess of the designer's intention, the weight originally proposed having been forty-seven tons. There is evidence throughout the whole structure of remarkable skill and ingenuity in providing against the many unknown conditions that will be met with when running at the velocities intended, and whatever may be the result finally attained, Mr. Behr deserves the utmost credit for anticipating and preparing for every difficulty that can be foreseen.

As will be seen from the sectional view, the roof of the carriage is double, the distance between the outer and inner casings being sufficient to admit of a device for supplying air to the interior of the carriage without any violent draught. Ventilators are placed on the roof, and air flows through them into the space between the casings, where it is met by a series of baffle plates, that gradually reduce the velocity of the current, until it flows through openings in the inner casing, at a convenient rate. As will be seen from the longitudinal section, the carriage is lighted by incandescent lamps, taking their current from the main circuit. The triangular chamber in the bow of the carriage is reserved for the driver, who has at his command various devices for controlling the current, manipulating the special air brakes, and putting on the hand brakes for bringing the carriage to rest. The switch gear is very complicated, and would doubtless be capable of much simplification. Its functions are to couple the motors, two in series when starting, and afterward two in parallel, and for shunting the magnetic fields so as to obtain the maximum speed. Resistances are inserted in series with the motors when first switching on and also when they are first thrown into parallel. The switchboard, as well as the motors, was designed and made by Messrs. Thomas Parker, Limited, of Wolverhampton. One of the original features of the Behr carriage is the arrangement adopted for checking the carriage when running at a higher speed than could be controlled by existing forms of brakes. For this purpose the tapering ends forming the bow of the carriage are fitted for their whole height with a series of louver plates turning on vertical spindles, the lower ends of which are extended beneath the floor and carry worm-wheels that gear into a series of worms on a horizontal shaft. By operating the handwheel all the louver boards on each side of the bow are opened more or less at the will of the driver, and air resistances are created by the exposure of the inner sides of the louvers and the side plates of the frame. It is intended that as soon as the speed is reduced to convenient limits by this means, the stop should be completed by means of the hand brakes, which can be applied to each wheel of the carriage.

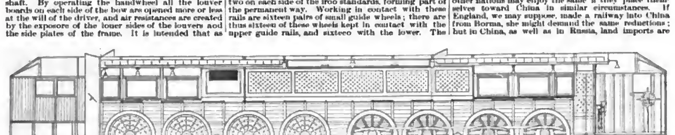
The carriage is supported by eight wheels, 4 ft. 6 in. diameter, mounted in two four-wheeled trucks which are coupled at the center by means of a universal joint. The very short axles of the wheels run in boxes mounted on pedestals that are riveted to the main frame, and the carriage is hung on the boxes by means of cast-steel curved hangers to springs, one on each side of the wheels, the springs being beneath the axles. The general arrangement is shown in the sectional view. There are four electric motors, placed in the hold of the carriage. Thus two wheels of each truck are driven, the two outer wheels running free. The motors are of the four pole type, with toothed armatures wound with Eickmeyer's coils. Each motor is designed for developing 150 horse power when furnished with a 700 volt current and running at a speed of 600 revolutions per minute. As will be seen, the motors are bolted to the lower deck of the carriage, and a rigid distance piece connects the motor shaft with the axle of the driven wheel, the speeds of each being equal. The means of transmission is a Renold steel chain, which appears to have given satisfactory results when tested at the Gloucester works. As already explained, the motors are controlled by a switchboard placed in the driver's compartment. When the carriage is started, the four motors are connected in "two-parallel-two series" with a resistance in series between them. This resistance is gradually removed, and the connections are then shifted, until all of the four motors are connected in parallel with the resistances in series. This resistance is then cut out, and the motors in parallel are connected directly across the full electromotive force. If a higher speed is desired than is obtainable by the normal mode of working, the series field winding of the motors is shunted through the resistances. The current for the motor is taken from a conducting rail laid on the sleepers with insulators interposed for the whole length of the track. The current is supplied to the motors through collectors on the carriage, kept in contact with the conductors, and the position of which is shown in the sectional view. The return circuit is made through the wheels of the trucks and the carrying rail.

Besides this carrying rail there are four guiding rails, two on each side of the iron standards, forming part of the permanent way. Working in contact with these rails are sixteen pairs of small guide wheels; there are thus sixteen of these wheels kept in contact with the upper guide rails, and sixteen with the lower. The wheels are 18 in. in diameter. Slots are cut in the steel plating of the carriage adjoining the rails for the wheels to pass through and make contact with the guide rails. The shafts are mounted at the ends of an adjustable frame, shown in the sectional view, and secured to the main frame of the carriage in such a way as to maintain the wheels in contact with the guide rails. The principal work that will be thrown on this device will be in passing round the sharp curves which are characteristic of the Tervuren experimental line.

The electric station which is to supply current for the Behr carriage is being furnished by the exhibition authorities, but unfortunately it is still far from being complete. Indeed, although we believe that at the present time about one-fourth of the ultimate power is available, some time must still elapse before the full energy will be available.



THE BEHR SINGLE RAIL RAILWAY—BOGIE TRUCK.



THE BEHR SINGLE RAIL RAILWAY—SECTIONAL VIEW OF CAR.

THE MANCHURIAN RAILWAY.

THE Times correspondent, writing from St. Petersburg, February 5, says: A commission of engineers now holding sittings here for the purpose of discussing technical questions concerning the construction of the Manchurian railway under the presidency of the chief engineer, M. Yugovitch, will leave St. Petersburg for Manchuria about the middle of March. The rest of the year will be spent in completing surveys. There will be considerable work in tunneling at both ends of the line, especially on the eastern section toward its junction with the Ussuri branch of the Siberian railway. Although the articles of association fix next August as the latest time for beginning work, the actual construction of the line is not likely to be commenced before 1898. The Eastern Chinese Railway Company are contracting for about 15,000 tons of rails annually during six years, and will probably order several steamboats and a large number of barges for the river Sungari. The increased number of boats belonging to the two Amur steamship companies are still unable to cope with all the demands created by the new situation. The Sungari, if not too shallow for heavy goods, would be the best channel for transporting railway material from the Amur on to the route of the line through Manchuria. If possible, the Manchurian line will be begun at both ends, but unless the Sungari can be used as suggested, there will be some difficulty in getting the necessary material on to the spot, especially as the Transbaikal section of the Siberian Railway, of which the Manchurian line will be a continuation eastward, will not be completed for some time to come. It will be easier probably to transport the rails and begin from the eastern end at Nikolsk. A sufficient number of native laborers, it is expected, will be found in the country at very cheap rates. In all probability the surveying and working parties will be escorted by Cossacks. In fact, travelers from Siberia report that Cossacks have already been seen in the frontier settlements on Chinese territory. The company, however, say they will have no need of Cossacks unless their rights and property are seriously endangered, and the police force which they are now taking steps to enroll prove unequal to the occasion.

Other travelers' stories bear upon some kind of projected railway from Kiakhta, which would be far more important and profitable for strategical and commercial reasons, but we may assume that the Russians will have enough to do for the present with the line they have already undertaken to build. There is certainly an idea entertained on the Chinese side of effecting a junction between the Chinese railway running to the Manchurian border near the Gulf of Pe-chi-li and the Russian line from Siberia. It must be borne in mind that no one has yet seen the text of the contract made between the Chinese government and the Russo-Chinese bank, which may or may not contain more than has been only incidentally disclosed by publication of the charter granted by the Russian government to the railway company formed by that bank. Whether or not that contract was a tripartite agreement in which the Russian government also took part, as some persons are inclined to believe, there is no doubt that the disclosure of so much of its contents as appeared necessary was calculated to discredit the alleged treaty between the two governments, and the latter as published in the English press is now commonly regarded here as the draft of a compact solicited but never really concluded.

In regard to a remark some time ago in the Times as to the reduction of duties made by China for the benefit of Russian importers via the Manchurian Railway, it is pointed out that it is a mistake to suppose that the favored nation clause will entitle other nations to claim a similar privilege. This advantage is given by China to the Chinese Eastern Railway Company—a private association—and not to the Russian government. The reduced duties, besides entire exemption for transit goods, are simply for overland imports, and other nations may enjoy the same if they place themselves toward China in similar circumstances. If England, we may suppose, made a railway into China from Burma, she might demand the same reductions; but in China, as well as in Russia, land imports are

taxed differently from those received at the seaports, where all nations in this respect are treated alike. For example, tea imported into Russia overland through Kiakhta is charged with 25 per cent. less duty than tea entering Russia by sea. There is even a differential tariff for the importation of seaborne coal, which is much higher at St. Petersburg and the Baltic ports than at those of the Black Sea. It is not a government that is favored by a reduction of duties on goods introduced by means of the Manchurian Railway, but a private company. The privilege was granted in the concession in lieu of a subsidy to help to make the line a profitable undertaking. The Russian vice president, M. Kerbets, one of the ablest railway men in Russia, will consider himself in the service of the Chinese government, like Sir Robert Hart at the head of the Chinese customs. I may add, in conclusion, that M. Kerbets is also chief director and manager of the Vladikavkaz Railway Company, which is now extending its line from Petrovsk along the coast of the Caspian through Derbend to Baku, and will shortly begin another most important and difficult railway across the mountains of the Caucasus from Kuban district to a point on the Black Sea coast near Sukhum Kaleh, thence to a junction with the railway of the Transcaucasus from Batoum. When these two railways are completed the Transcaucasus will be directly connected with the main Russian system at both ends of the great mountain range abutting on the Black Sea and the Caspian.

HURDY-GURDY OR TANGENTIAL WATER WHEELS.

By PHILIP R. BJORLING, in the Colliery Guardian.

TANGENTIAL water wheels, like the Poncelet water wheel, in some respects resemble turbines, but they are simpler in construction, less liable to choke or get out of order, and can be worked by much greater height of fall than any turbine yet designed. They may be termed tangential reaction water wheels, the power being derived primarily from the pressure due to the head of water supplied by a pipe discharging upon the wheel buckets by a nozzle, the size of which is proportional to the amount of water available and head and power required. Some makers of these wheels guarantee 80 per cent. effective duty out of the power due to the height of fall, and some even claim that as high as 88 per cent. has been obtained. The original bucket consisted of flat plates, but it was afterward found better to receive the stream on a strip edge, so as to divide it, and terminate the sides of the bucket by a curve, so as to reverse the current of water. The principal difference in these water wheels constructed by the various makers consists in the shape and position of the buckets, and in the manner in which they are regulated.

The Dodd "sigmoidal" bucket, illustrated in perspective in Fig. 1, is provided at the center with a midfeather which divides the water jet.

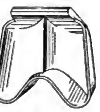


FIG. 1.

Fig. 2 illustrates, also in perspective, Mr. Knight's bucket, in which there is no midfeather, but the inventor claims the advantage that he can apply a larger amount of water with a single nozzle, and can, therefore, use his wheels for low heads.

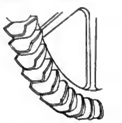

FIG. 2.

The Berry wheel is illustrated in Fig. 3, in which A is the line of the jet meeting the buckets, B, which are secured to the wheel with bolts. The buckets are radial and their convex face presented to the jet; they

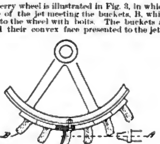

FIG. 3.

are formed with a double curved bottom, presenting a sharp dividing apex in the center which splits the stream of water discharged on the wheel, and also curved in the opposite plane so that they will present a convex surface, normal to the stream of water, in all positions of the buckets.

The wheel which is most extensively used, especially on the Pacific coast, is the Pelton water wheel, one of which, with a single nozzle, is illustrated in elevation (Fig. 4), enlarged sectional elevation of bucket (Fig. 5), and plan of the same (Fig. 6). This wheel is manufactured in this country by Messrs. Frazer and Chalmers. The buckets, A, secured to the periphery of the wheel, B, are of a peculiar shape, and divide the jet of water in such a way as to develop its full power, while in emerging they sweep against the curved sides with a reactionary influence, which has the effect of prolonging the impact. It is also by this means deflected from the wheel so as to offer no resistance to its motion. The

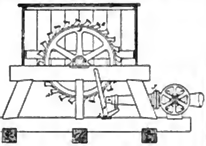

FIG. 4.

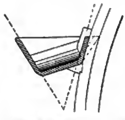
power of this class of water wheel does not depend upon the diameter of the wheel, but upon the head and amount of water applied to it. Where a great power is wanted under a comparatively low head, a larger wheel is necessary to admit of buckets of sufficient size to deal with a large stream. Wheels of greater diameter are also desirable in many cases as a means of reducing the speed, even in cases where the smaller wheels would furnish all the power required. For instance, buckets suitable for smaller wheels are frequently fitted on to wheels of larger diameter to reduce the speed; this is particularly the case when light heads are dealt with. The two or three nozzle wheels are only for the purpose of increasing the power by the use of a large amount of water, and the head is so low that a single stream or jet will not give the power required. These wheels have been working successfully with heads varying from 10 to 1,680 ft. One of the great advantages of this class of wheels is the facility with which wide variations of power can be produced without impairing the efficiency. This can be accomplished in three ways, namely:

1. By changing the size of the nozzle tip or tips, and by that means varying the size of jet or jets thrown on

FIG. 5.



the wheel, the power of which can be varied from its maximum capacity down to one-fourth of its power without appreciable loss, thus adapting it to a full supply of water when obtainable, or to a reduced quantity when from any reason the supply is limited.

2. The second method of varying the power is shown in Fig. 4, which illustrates a 6 ft. wheel fitted with deflecting nozzle, H. It is made 3 ft. 5 in. in length, attached to a ball and socket joint, J, and raised and lowered by a bell crank lever, K, working on a fulcrum, L. By this arrangement the whole or any part of the stream can be thrown on or off the wheel instantly, thus affording such variations of speed and power as may be desired to accommodate any change in load or supply of water. The amount of water wasted is so small as in most cases not to be worth consideration.

3. When great steadiness and even running is important, and the head is not sufficient to give the required power with an ordinary wheel of one jet, a wheel of larger diameter, allowing of a larger jet, is to be recommended, instead of using two, as the deflecting nozzle with a governor attached can only be used

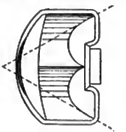


FIG. 6.

with a single nozzle. In such cases the nozzle lever is actuated automatically by a governor.

The peculiar feature of Mr. C. L. Hett's patent hurdy-gurdy wheel consists in an improved regulating nozzle, by means of which the power of the wheel can be changed without raising or lowering the nozzle, thus dispensing with the necessary ball and socket joint, and obviating waste of water.

The arrangement of the nozzle, when the regulation of speed or adjustment is performed by a hand wheel, is illustrated in Fig. 7, in which A is a casting pro-

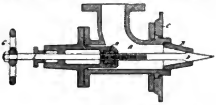

FIG. 7.

vided with the inlet branch, and bolted to the wheel casing, C; B is the nozzle into which is fitted a plug or spear, D, at the end of the screwed spindle, E, the latter working in a gun metal nut, H, and actuated by means of the hand wheel, G. It will be clearly seen that by turning the hand wheel the spear is either pushed into the nozzle, closing it, as shown in the illustration, or opened more or less according to requirements.

Mr. Hett's automatic nozzle is shown in sectional elevation, Fig. 8. It consists of the spear, A, and nozzle, B, as in the previous case, but in this instance the spear is actuated by means of the head of water acting on a piston in a hydraulic cylinder, the admission and discharge of water to and from the cylinder being regulated by a high speed centrifugal governor. In the illustration, C is the hydraulic cylinder and D the piston, the latter being secured to the spear. E is a piston valve, connected to the valve spindle and lever with the governor, H. The governor is driven in the usual way, with a belt from the wheel spindle. J is a passage for admitting water under pressure from the

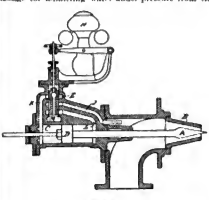

FIG. 8.

main inlet. K and L are ports for admitting and allowing the escape of water to and from the hydraulic cylinder. M is the discharge pipe. The action of this governing apparatus is as follows:

Assume the wheel to be running at its normal speed, the governor holds the valve, E, in midposition, as shown in the illustration, and the piston, D, in the hydraulic cylinder is in equilibrium and stationary. If the speed varies, the governor either rises or falls, moving the valve, which admits water under pressure to one or the other side of the piston, as the case may be, at the same time opening the delivery pipe and allowing water on the opposite side of the piston to escape. The piston and spear move and admit or cut off water to the wheel until the normal speed is again obtained. Two or more wheels may be used on the same shaft, where the head of water is low, to admit of getting the power desired from one wheel.

In Cadle's patent duplex hurdy-gurdy water wheel

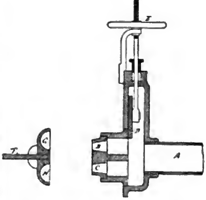

FIG. 9.

the buckets fit on the disk of the wheel into recesses, which are cast there to receive them. They are held in position by a single bolt passing through opposite buckets. No strain due to the impact of the water

comes upon the bolts; they simply serve to hold the buckets in their places, all the strain being taken by the lugs and ribs upon the disk into which the buckets fit.

Fig. 9 is a sectional elevation through the sluice, nozzles and buckets of one of the Cadle water wheels. A is the main pressure pipe; B and C the nozzles, regulated by the slide, D, and hand wheel, E; F is the rim of the wheel, and G and H the buckets. It will be noticed that the jets strike the bottom of the bucket, and turn the stream of water back to the direction from whence it came. In this wheel the slide is made to open one side of the nozzle at a time, so that when only one-half of the power is required the slide is only drawn half open.

Cadle's patent quadruple tangential water wheel is illustrated in sectional elevation Fig. 10. In this there

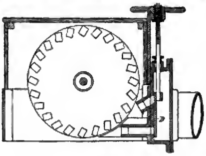

FIG. 10.

are two pairs of double nozzles, one pair above the other. The same slide, D, controls all the nozzles, it being so proportioned that when it is opened it first uncovers the lower nozzles, and a further movement opens the upper pair. By this arrangement the power of the wheel is doubled, and when only half power is required only the lower nozzles are opened.

The James Leffel cascade water wheel has the water admitted to it by one, two or more nozzles without decreasing the useful effect of the water; but the percentage remains the same, whether one or more be used. Each nozzle increases the power in the direct proportion of the increase of their number, requiring a proportional increase in the quantity of water. The peculiarity of the construction of this wheel is that the buckets are arranged alternately on each side of a central, sharp, continuous dividing ridge, projecting a little in front of the entering edge of the bucket. The dividing ridge has a sharp cutting edge, which serves to divide the jet of water before it reaches the buckets, and to keep it continuously divided into equal portions, so that each portion of this single jet is received separately on each side of the dividing ridge. Each series of buckets is so arranged that they catch the water alternately. It is claimed for this wheel that the alternate arrangement of buckets secures greater steadiness of motion, as it is equivalent to twice the number of buckets, and the forces are therefore distributed more regularly on the wheel.

The latest, and to all appearance the best, hurdy-gurdy or impulse water wheel is the one patented by Mr. F. M. F. Cazin, of New York, and manufactured by the American Impulse Wheel Company. This wheel is illustrated in Fig. 11. The slide, A, is so arranged

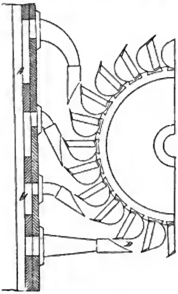

FIG. 11.

that one, two, three, or four nozzles can be used as required. Fig. 12 is a front view of a pair of buckets, Fig. 13 a plan, and Fig. 14 a cross section. The buckets are secured in their places on the rim of the wheel by means of a dovetail and bolts. The jet in an impulse wheel loses some of its maximum efficiency by the weight of the water being carried for some distance without support before striking the wheel, so that in this respect it is inferior to the turbine. In the Cazin wheel the nozzle mouth is shaped closely by and to the extreme circle in which the bucket revolves, as shown at H. It will be noticed that the bucket is curved every way, so as to perfectly reverse the current in every direction, and there is a lip which guides the jets into the bucket presented to it, and directly that is passed, into the next bucket. The diameter of jet is, as a rule, equal to the radius of the bucket cavity, which gives to half the jet four times its original width of space in which it may turn in its own course. For economical reasons the jets are made two-thirds of the

FIG. 12.

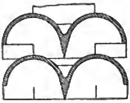

FIG. 13

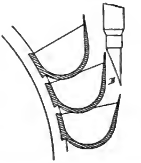

FIG. 14.

diameter of the bucket centers, as their diameter may be applied, which gives to the jet halves three times their width as space to inverse their direction of motion.

THE COEFFICIENT OF TRACTION OF CARRIAGES.

THE rapid progress of automobile locomotion has made the question of the coefficient of traction of the different tires used on the wheels of vehicles the order of the day. Opinions are as yet much divided, and it requires nothing less than direct and accurate experiments to solve the problem definitely and to show, without possible dispute in the future, the superiority of the pneumatic tire over that of iron and solid rubber.

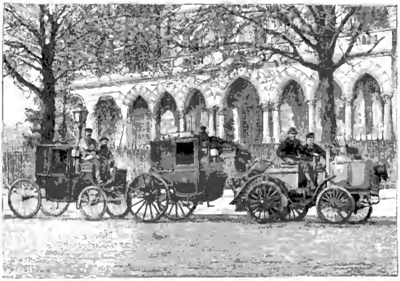
Some convincing experiments were made last year by M. Michelin, but the figures obtained were merely comparative and did not furnish numerical results capable of serving for the calculation of the power of motors to be placed upon horseless vehicles. The experiments have been recently resumed under more favorable conditions in the vicinity of Paris, by means of the singular train shown in Fig. 1. But, before describing the apparatus, a word as to the definition of the factors to be measured. As well known, in order that a vehicle may be hauled upon a road, which, in order to simplify the problem, we may suppose to be level, it is necessary that there shall be exerted a certain stress—a horizontal force, that depends upon the nature of the road, the weight of the vehicle, the nature of the tires and the suspension, rolling and speed of the vehicle. Such tractive force is measured in kilogrammes, and the ratio of such force in kilogrammes to the weight of the carriage hauled (likewise measured in kilogrammes) constitutes the coefficient of traction, which is generally expressed in kilogrammes per ton, or, more simply, in thousandths, with a view to avoiding the use of fractional numbers.

The experimental problem, therefore, consists in causing a carriage of known weight, whose wheels are provided with the tires to be studied, to be hauled over roads of varied character and in measuring the tractive stress exerted at every moment. From this is deduced the coefficient of traction by the simple calculation just mentioned.

In the experiments made by M. Fonvielle, under the direction of M. Michelin, a De Dion steam locomotive hauled the carriage through the intermedium of a registering dynamometer installed in a coach placed between the locomotive and the carriage hauled (Fig. 1).

The dynamometric coach belongs to the Compagnie Générale des Voitures. The dynamometer consists, in principle, of a double spring arranged transversely in the carriage. The middle of one of the bands is fixed to the carriage, and the middle of the other is attached directly to the vehicle to be hauled through an iron bar that traverses the coach. Under the tractive stress, the spring bends, opens, and leaves its position of equilibrium by a length proportional to the stress exerted.

If a pencil be placed vertically upon the movable part of the spring, and a band of paper be made to unwind transversely and with a uniform motion under the point of the pencil, the latter will trace a curve that will permit of determining the amount of the



Carriage under experiment. Dynamometric carriage. Locomotive.

FIG. 1.—DYNAMOMETRIC TRAIN USED IN DETERMINING THE COEFFICIENT OF TRACTION OF CARRIAGES.

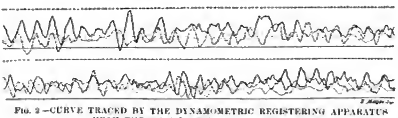


FIG. 2.—CURVE TRACED BY THE DYNAMOMETRIC REGISTERING APPARATUS UPON THE QUAI PRESIDENT CARNOT ROAD.

——, iron tires; — — —, solid rubber tires; ......, pneumatic tires.

stress at every instant, as well as the mean value of such stress upon a given length of roadway.

In order to determine the speed, another pencil bears against the paper continuously and is lifted for an instant, at every revolution of the wheel, through a mechanism actuated by the latter. It thus traces an interrupted line that permits of measuring the speed of the vehicle deduced from that of the unwinding of the paper, from the number of interruptions and from the length of the circumference of the wheel controlling the pencil.

The diagram in Fig. 2 shows the traces obtained with different tires (solid rubber, pneumatic and iron) at a speed of 22 kilometers (13 miles) an hour upon the old, dry and somewhat broken up macadamized Quai President Carnot road, at Suresnes. The experiments were made in replacing the wheels of the carriage and in equalizing their weight. It will be remarked that the curves relative to the pneumatic tires are not so high as and much more regular than those that correspond to the iron ones. The tractive stress is, therefore, more regular, and the shocks less perceptible with the pneumatic than with the solid rubber tire.

The mean values of the coefficients of traction deduced from these experiments, in integrating the results obtained upon runs of 1 kilometer (0·6 of a mile) are summed up in the following table:

CONDITIONS OF THE EXPERIMENT.

	Tires.		
	Iron.	Solid Rubber.	Pneumatic.
I. Boulevard de la Seine: (Level.)			
Good macadam, hard, dry and dusty.			
Wind ahead, v = 11·7 km. per hour	27·6	24·5	22·6
Wind behind, v = 11·7 " "	25·6	22·6	20·6
Wind ahead, v = 19·7 " "	34·4	29·9	24·8
Wind behind, v = 19·7 " "	27·6	23·2	23·8
Good macadam, hard and slightly muddy.			
v = 11 km. per hour	27·4	26·5	24·0
v = 20 " "	39·9	35·6	31·8
Good macadam, water soaked.			
v = 21 km. per hour	45·6	42·6	35·0
II. Boulevard de Versailles: (Grade of 40·1000.)			
Good macadam, hard, dry and dusty.			
v = 11 km. per hour	62·1	61·1	57·2
v = 19 " "	73·6	64·1	59·6
III. Route of St. Germain: (Grade of 6·1000.)			
Ordinary pavement, slightly rough and dry.			
v = 11 km. per hour	40·8	40·1	36·1
Ordinary pavement, slightly rough and with sticky mud.			
v = 18 km. per hour	54·9	57·6	44·0
Ordinary pavement, slightly rough and with half dry mud.			
v = 12·5 km. per hour	44·5	41·9	38·0
v = 20 " "	52·2	56·0	40·7
IV. Quai President Carnot: (Level.)			
Old macadam, somewhat broken up.			
v = 22 km. per hour	30·8	28·0	22·5

These figures bring clearly into relief the influence of speed as well as that of the wind upon the coefficient of traction. The superiority of the pneumatic over the iron tire, which is only 10 per cent. at a feeble speed and upon a good road, rises to 33 per cent. when the road is broken up and the speed reaches 22 kilometers an hour.

It may be said, without exaggeration, that the use of the pneumatic tire permits of a gain of from 20 to 25 per cent., on an average, upon the coefficient of traction, and, consequently, upon the power of the motor and consumption of fuel.

Such advantages are not to be disregarded, and although they have been recognized in principle by all competent specialists, we have to be thankful to M. André Michelin for having fixed the extent of their importance by accurate experiments and by means of registering apparatus of which the impartiality is beyond question.—E. Hospitalier, in La Nature.

SIX N. H. P. TRACTION ENGINE.

WE illustrate below an improved type of traction engine exhibited at the Bath and West and Southern Counties Agricultural Show by Messrs. Ruston, Proctor & Co., Limited, Lincoln, which possesses several novel features worthy of more than passing attention, particularly a single eccentric, reversing gear, illustrations of which are given in Figs. 1, 2, 3, and 4 herewith. The engine shown is particularly adapted for driving plowing tackle, thrashing and other machinery. It has a boiler of comparatively large capacity, the plates of which are of Siemens-Martin mild steel, and intended to withstand a working pressure of 120 pounds per square inch. The horn plates are of steel, riveted to the fire box and to each other, making a rigid frame, while the top of each plate is recessed to receive the

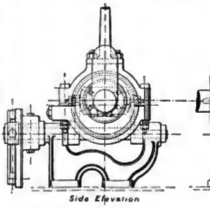

FIG. 1.

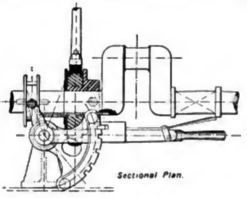

FIG. 2.

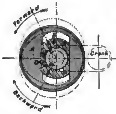

FIG. 3.

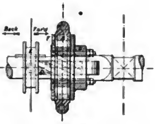

FIG. 4.

SIX N. H. P. TRACTION ENGINE.

crank shaft pedestals. The main portion of the single eccentric reversing gear consists of two moving pieces only, the eccentric, A—Figs. 3 and 4—which has an elongated slot cut centrally with the crank shaft and at right angles to the crank positions, made to fit and move freely on flats cut upon the boss of the main driving plate, C, and a sliding bar of steel securely fastened to the clutch, E, so that both may be moved easily in either direction parallel to the axis of the crank shaft. Upon the outer face of the bar, D, is formed a series of inclined teeth, which engage with similar spaces and teeth cut on one side of the slot in the eccentric, A. It will be clear that on moving the clutch, E, and bar, D, from side to side along the crank shaft, the eccentric will be made to rise and fall above and below its central position, as shown by the dotted lines in Fig. 3. The clutch, E, is driven by a feather key, upon which it slides freely, so that while it rotates with the crank shaft it can be easily pushed in and out by the clutch dies and reversing levers. The bar, D, in addition to being milled out at the back to fit the radius of the crank shaft, is fitted in a slot in the main driving plate, C, so that it is impossible for any twisting movement to occur which would cause a locking of the gear. A cover plate, F, is provided, and firmly secured by bolts passing through the main driving plate, C, so that the eccentric A, is held freely but firmly by the two plates, F and C, between which it rises and falls. It will be clear that the center of the eccentric is thus moved from the "forward" position, a, perpendicularly down the lap line, a, b, of the Zeuner diagram to b, which is the center of maximum throw for the "backward" motion. The effect of this movement is to vary both the travel and angle of advance of the eccentric. The chief factor in the success of this gear is the fact that while the rotation of the eccentric is easily performed by the large flat surfaces on the driving boss, C, none of the work of driving the valve is thrown upon the bar, D, which is thus free to move the eccentric and hold it in any required position with very little effort on the part of the driver.

We are indebted to The Engineer, of London, for the cuts and description.

HOW CLOTH IS DYED SEVERAL COLORS AT ONCE.

THE following methods of dyeing a piece of goods with several colors simultaneously are now largely used in Europe, according to the Textile World. All the methods are quite simple in theory, depending chiefly on the various absorptive powers of different fibers for different dyes.

There are but few dyes that tinge wool, silk, and cotton equally with the same preparation. The one or the other remains undyed, according to the kind of fiber and method, and may be dyed subsequently with another dye. . . . . The trifling quantity of dye mechanically precipitated upon the dyed fiber must be stripped first, however, but in such a manner that the color lake formed upon the dyed fiber is either not at all or at most very little attacked. A simple boil in condensed water or in a weak bath of acetate of ammonia suffices frequently.

Two-color half woolen weaves are generally produced in such a way that the wool is dyed first; the cotton is then mordanted with tannin and antimony, or antimony salt, and dyed with basic dyes from cold to warm. . . . .

Differences of temperature also influence frequently the fixation of a dye upon one of the fibers, and its indifferent behavior to the other. For instance, the so-called changeable effects upon piece-dyed gloria. These fabrics generally consist of woolen warp and silk filling, and both fibers are dyed in a different color, say the wool red, the silk green; wool garnet, silk blue, etc. The wool is dyed in a boiling bath; . . . the dye adhering to the silk is stripped by treating for thirty minutes with boiling water, and the silk is next dyed in a cold bath.

Still more curious effects can be produced when the different fibers have been treated, before weaving, with different chemicals.

As many mordant dyes furnish different colors according to the mordants used, it will become possible to produce in this way more than two colors. For instance, alizarine red gives a bordeaux upon chrome, a high red upon alum, and lilac upon iron. Consequently, by weaving together yarn treated with these three mordants, and dyeing the weave in an alazarine bath, a triple colored weave will be the result, and in case unmordanted yarn was also used, a fabric of four colors will be obtained. Again, the cotton dyer can, with different mordants, produce different shades of the same color. For instance, the tone of many colors dyed upon a sumac differs from that upon tannin-antimony, or antimony. Yarn treated with these two mordants and woven together with unmordanted, next dyed in two baths, gives a triple colored weave.

INDIAN INK MANUFACTURE.

AN interesting account of the manufacture of the so-called Indian ink, which is made only in the Anhui province of China, is given by Mr. Frazer, British consul at Wuhu, on the Yang tsze, in his last trade report. It is more correctly called China ink—encre de Chine—and from Anhui it goes to every part of China and all over the world. In 1895 about two tons of it, valued at £564, were exported from Shanghai to foreign countries. The materials with which this beautiful black ink is made are sesamum or colza oil, or the oil expressed from the poisonous seeds of a tree extensively cultivated in the Yang-tsze valley, and also well known in Japan. To this varnish and pork fat are added. The lampblack made by the combustion of these substances is classed according to the materials and the grade of fineness, and also according to the time taken over the process of combustion. The paste made of this lampblack has some glue added, and is beaten on wooden anvils with steel hammers. Two good hammerers can prepare in a day 80 pieces, each weighing half a pound. A certain quantity of musk of the musk deer or of Baroos camphor, for scenting, and gold leaves, varying from 20 to 100 to the pound, are added to give a metallic luster. The materials thus prepared are moulded in moulds of carved wood, dried, which takes about twenty days in fine weather, and adorned with Chinese characters in gilding. About 30 or 32 average-sized sticks of ink go to the pound. The price varies from 2s. or less per pound to as much as £7, there being over a dozen different grades. Nearly all writing is done by the natives throughout China, Japan, Korea, Tongking and Anam with this China ink, rubbed down on a stone ink slab and applied with a rabbit brush of sable, fox or rabbit hair, set in a bamboo holder, and, when not in use, carefully covered with a protecting brass cap. The superior kinds of this ink appear to be used in China and not exported.

PHOTOGRAPHY IN COLORS.

PROF. GRABY read a paper on photography in colors before the Académie des Sciences in Paris recently, and not only explained every detail of the process and gave the exact formula to be followed, but also showed some remarkable photographs in colors taken by himself.

In almost all the attempts made previously to reproduce color in photography the processes have depended upon the physical effects of the interference of light. Prof. Graby has depended entirely upon chemical action. His explanation of the process, as described in his paper, says the New York Sun, is as follows:

"When a plate of metallic silver is exposed in the dark to the action of chlorine, a series of chlorides is formed, ranging in color from yellow through red to blue. If the same plate be afterward exposed to light the action is reversed, the final result being yellowish white. If pure white silver chloride dipped in a bath of silver nitrate be subjected to feeble blue light, a blue subchloride will be produced which will retain a large proportion of the original chlorine. Similarly a red subchloride can be obtained, containing still less chlorine. The yellow is secured by a less direct method, for, although a grayish yellow subchloride of silver can be produced, it is not sufficiently pure in color or capable of giving all tints. Consequently chromic acid or a chromate is introduced, giving a golden yellow complementary to the blue violet of the silver, which is degraded by the light, furnishing all the yellows imaginable.

"Under the influence of blue light the blue subchloride is not sensitive, and remains the same, but the red, if mercuric chloride be present, takes up chlorine and is converted into the blue. If chromic acid be present also the yellow becomes oxidized to blue, so that only blue remains.

"Under yellow light the chromic acid is not effective, but the blue and red—especially the former—are bleached, losing their chlorine and amalgamating with mercury.

"Under red light, the red subchloride remains unchanged, but the blue is changed by the red orange rays into red subchloride.

"White light produces blue or greenish yellow, according to whether the paper is exposed in the dry or moist condition.

"To secure permanency, the yellow is fixed by washing the print with acetate of lead, which renders the chromate insoluble. The blue and red are obtained by introducing bichloride of mercury and salt into the coating of the paper. These two substances keep up a state of equilibrium as regards the action of light on the chlorine, so that the blue and red subchlorides retain their composition indefinitely. This fixing can only take place after the white has been fixed, except on salted and albumenized papers, to which, however, the subsequent method of fixing the white cannot be applied. Therefore complete fixation can only be secured with gelatine papers, and this is the most important point of the discovery.

"The trouble found for a long time was that the violet-blue silver compound produced by the action of white light could not be removed without seriously affecting the blue of the print. The first method tried was one in which the white light rendered the gelatine soluble, as in the perchloride of iron process. It was found that the gelatine became less soluble according to the color of the print. White light rendered the gelatine completely soluble, yellow light a little less so, red still a little less soluble and blue almost entirely insoluble. The gelatine in melting removed the chloride, which would have become blue, subsequently to fixation, on exposure to light. Thus, in the first method, the yellow was fixed with acetate of lead, the white by washing with warm water, and the red and blue by salt and bichloride of mercury.

"The first method could only be carried out with paper prepared as follows: Gelatino-chloride paper is allowed to become blue, almost to the violet stage, by immersing it in a bath of

Water	100
Hydrochloric acid	4

and exposing it to diffused light, then dipping it, when dry, into

Water	100
Bichromate of potash	1

"It is dried afresh and exposed anew until all the gelatine is just rendered insoluble. The paper is then ready to be sensitized for colors in the following bath:

Water	4	ounces.
Nitric acid	10	drops.
Mercuric nitrate	1	drachm.
Hydrochloric acid	1½	"
Sulphuric acid	½	"
Chromic acid	45	grains.
Soda alum	90	"

"This paper must be employed wet. The results so obtained are most interesting. But for practical work the paper prepared in the second manner should be used.

"In this method the light renders the gelatine insoluble, as in the carbon process. Gelatino-chloride paper is treated with acid and blued as above, then dipped in a bichromate bath, and then in nitrate of mercury. When dry, it is printed so as to reproduce the colors. After this it is treated with acetate of lead; then the image is transferred on to another paper and washed, as in the carbon process. Finally it is passed through a bath of bichloride of mercury and salt."

SELECTED FORMULÆ.

Keeping Flies off Stock.—Try one of the following:

(1.)	Carbolic acid	1	ounce.
	Oil of pennyroyal	2	"
	Spirit of camphor	2	"
	Oil tar	4	"
	Glycerine	2	"
	Fish oil	2	"
(2.)	Pine tar	1	part.
	Fish oil	2	"

The oil is used to keep the tar from sticking; if fish oil cannot be obtained, lard oil may be used. An addition of 2 ounces of crude carbolic acid to the gallon of paste will improve it. Paint the mixture on when necessary.

(3.)	Black oil	1	quart.
	Crude carbolic acid	4	ounces.
	Fish oil, enough to make	1	gallon.

—Pharmaceutical Era.

Preservative for Eggs.—Various preparations for preserving eggs for winter use are sold to unsophisticated housewives, and usually at a good profit for the manufacturer. The principle upon which most of such compounds act is that of excluding the air; almost any wax or varnish will serve this purpose. There are two requisites—have the eggs fresh and clean and put them up as late in the season as possible.

One very ancient and universally applied method consists in dipping the eggs into melted wax or paraffin. We append a formula for preparing a coating solution which duplicates one very extensively sold:

Gelatine	½	ounce.
Borax	⅛	"
Water, to make	10	"

Dissolve gelatine in the hot water in which the borax has been previously dissolved; bottle. If too stiff, warm the solution; rub on the eggs, or dip the eggs in the solution.—Bulletin of Pharmacy.

How to Make Potpourri.—The never failing delight of a rose (or potpourri) jar is known only to its fortunate possessor; yet it is so easy to prepare one, and, once prepared, so easy to keep it at the point of perfection, that the wonder is they are not more frequently enjoyed. The flowers should be gathered in the early morning, and tossed lightly on a table in a cool, airy place, to lie till the dew has evaporated; then put them in a large glass jar, sprinkling salt over ½ in. layers of the flowers. This can be added to from morning to morning till enough flowers for the purpose have been gathered, letting them stand in the jar for ten days after the last are put in, stirring the whole every morning. Have 1 oz. each of cloves and allspice, coarsely ground, and as much stick cinnamon, broken and shredded fine; transfer the flowers to another jar, and scatter the spices, mixed together, in layers; cover the jar tightly, and let it stand in a dark place for three weeks, when the stock will be ready for the permanent jar. Whatever this jar is, be sure it is provided with a double cover.

Have ready ¼ oz. of mace and ½ oz. of allspice and cloves, all coarsely ground—or pounded in a mortar—half of a grated nutmeg, ¼ oz. of cinnamon, broken in bits, 1 oz. of powdered orris root, and ½ lb. of dried lavender flowers. Mix these together in a bowl, and proceed to fill the rose jar with alternate layers of the "stock" and the mixture of spices, etc. A few drops each of several essential oils—rose, geranium, bitter almond and orange flower are good—should be dropped upon the layers as you progress, and over the whole pour 1 oz. of your favorite toilet water or eau de cologne. This is sufficient to fill two quart jars, or one very large one, and it will keep for years; from time to time various sweet things may be added to it, as a few tuberoses or a spray of heliotrope. If the jar be left open for a half hour every day, it will fill your rooms with a delicate, indefinable spicy fragrance, very refreshing and delightful, and unlike any other perfume. The flowers chosen should be those having agreeable perfume, roses, pinks, violets, verbena, heliotrope, acacia, balm, lavender, etc.

Photographic Hints and Formulas.—

From Liesegang's Photographischer Almanach.—(Amer. Photo. Jl.)

Toning Bath (sulphocyanate of ammonium).—Two solutions are to be prepared:

(a.)	Water	1	liter.
	Sulphocyanate of ammonium	30	grms.
	Hyposulphite of soda	5	"
(b.)	Water	200	c. cm.
	Chloride of gold	1	grm.

For use, pour 40 c. cm. of (b) into 200 c. cm. of (a). If in reversed order, the bath will be precipitated.

Combined Toning and Fixing Bath.—

Water	1	liter.
Hypo	175	grms.
Alum	20	"
Sulphocyanate of ammonium	10	"
Common salt	40	"

After a short time this solution becomes turbid; it is then to be left to settle for eight days, then decanted and filtered, then add:

Water	100	c. cm.
Chloride of gold	1	grm.

Mountant for Silver Prints.—

Gelatine	100	grms.

Swell in cold water, the superfluous water is then poured off and the gelatine dissolved by aid of a gentle heat. Then add with constant stirring:

Water	30	c. cm.
Alcohol	150	"
Glycerine	50	"
Carbolic acid	20	drops.

This permanent non-cockling mountant thickens in the cold. For use, the bottle or jar is to be placed in warm water, which liquefies the mass; it is then ready for use.

ENGINEERING NOTES.

Germany's highest bridge is over the Wupperthal, at Mungsten, near Remscheid, back of Elberfeld. It is 360 ft. high and 1,630 ft. long, the central arch having a span of 530 ft. The only higher bridge in Europe is the Garabit viaduct, 405 ft. high, in southern France. The Mungsten bridge was opened for railway traffic on July 1.

A new experimental locomotive is to be fitted up in the engineering laboratory of the Purdue University, the present engine, which has been six years in use, and has run the equivalent of 20,000 miles, being sent on to the road. The new engine, which, like its predecessor, is being built by the Schenectady Locomotive Works, will be arranged to work either compound or simple. Several sets of cylinders are to be provided, the largest being 30 in. in diameter.

The exports of steel rails, in tons, were as follows:

	1895.	1896.
United States	8,807	71,303
England	457,352	749,106
France	10,585	15,782
Germany	162,246	181,577
Belgium	86,452	97,572

It will be seen that the exports from the United States increased about eightfold in one year.—Centralblatt der Walzwerke.

A revolving observation tower is being erected at Great Yarmouth in honor of the Queen's Jubilee. The design comprises a strong hexagonal steel tower 150 ft. high by 14 ft. in diameter, surrounded by a circular structure or elevator. This elevator is raised and lowered by four strong cables, each of which is capable of performing the work alone. On this elevator is a circular platform fitted with rollers, and intended to revolve upon the elevator. This platform is provided with revolving chairs accommodating upward of 150 persons. While the elevator ascends and descends the tower the platform revolves around it, thus affording an uninterrupted and unsurpassed view of the surrounding country. The elevator is operated by powerful engines, and the platform is propelled by an electric motor.

A new balanced compound locomotive, which is the property of the Balanced Locomotive and Engineering Company, of New York City, has been received at Purdue University, where it is expected it will soon be tested on the locomotive testing plant of that institution. The tests will be conducted by Professor Goss, acting under the direction of Mr. George S. Morison, vice-president of the company. From the peculiarity of the design of many parts of this engine, the results of the tests will be awaited with much interest by railway men. This engine is of the ten-wheel Atlantic type. It is a four-cylinder compound, each cylinder being independently connected to the driving axle. No eccentrics are used, the valve mechanism being operated conjointly from the crosshead and crankpin. The firebox also is a departure from the ordinary design.

In order to obviate the freezing of the Baltic canal, thus keeping it open for navigation as long as possible, says Die Vedette, the authorities tried to replace the fresh water of the canal by salt water; this could only be done from the Bay of Kiel, where the water contains on an average 1¾ or 1⅞ per cent. of salt, while at the other end of the canal, in the Lower Elbe, the percentage is about one-half per cent. only, and the level there is far more affected by the tidal movement than in the Bay of Kiel. Now, by leaving open a sluice near Brunsbuttel during low tide, the salt water, entering from the Baltic end, was caused to gradually expel the fresh water through the other end of the canal, and at the present time, both in the canal itself and in the lakes through which it flows, the fresh water fauna and flora are more and more disappearing, and are being superseded by salt water plants and animals from the Baltic.

In an article in Timber, London, on the value of teak for structural and mechanical purposes, the claim is put forth that such wood is really the most durable timber known, and of special importance to shipbuilders, being very hard, yet light, easily worked, and, though porous, strong and lasting. It is soon seasoned, shrinks but little, and on account of its oily nature does not injure iron. In southeastern Asia it is not only considered the best material for ship construction, but for house carpentry and other work where strength and other lasting qualities are required. It is rarely attacked by ants of the white species, and its rare durability renders it specially valuable in a climate like that of India, where the elements causing decay are so numerous and powerful, where dampness brings on rapid decomposition, and where the white ant devours without scruple. In the operation of cutting this wood is frequently girdled one or two years before it is felled, and, thus exposed to the wind, the action of the sun, and to the pumping capacity of the leaves, it seasons rapidly, and is drier and lighter than timber felled green.

The transportation exhibit of the Transmississippi Exposition will have a novelty in the way of a miniature locomotive and train, said to be the smallest train in operation in the world, says the Railway Review. The engine weighs 450 lb., its nearest competitor being a London locomotive weighing 5,000. Its length, with tender, is but 6 ft. 7½ in., and the size of the cylinder 1¼ by 2½ in. The tiny drive wheels are but 8 in. in diameter and yet it hauls six observation cars, in each of which two children can be comfortably seated. These cars are 41 in. long and 14 in. wide, and covered after the fashion of the ordinary observation cars in the East. The entire train, consisting of engine, tender, four observation cars, one box car and a caboose, is but an even 29 ft. in length. The engine carries 6 gallons of water in the tender tank and 5 in the boiler, which will furnish steam for two hours. Coal is hauled and shoveled out of the tender on the same plan that it is on the larger engines. In fact, the little engine is complete in miniature in every detail. Instead of using oil in the headlight, a little electric battery in the engine under the cab seat furnishes an incandescent which sparkles from the pilot like the diamond in a hotel clerk's shirt front.

ELECTRICAL NOTES.

The total production of electricity at the Paris centrals on the first of October, 1896, amounted to 1,775,000 watts from the dynamos and 1,610,000 watts from the accumulators.—Electrotechnische Rundschau.

In the month of April the erection of the telephone line from Berlin to Budapest was begun. It is to be completed in September, the total cost being estimated at 290,000 gulden, i. e., about $120,000. Of the total length, 1,000 kilometers, 440 are on German territory.—Electrotechnische Rundschau.

A car propelled by current from an accumulator covered the distance from Ludwigshafen to Frankenthal (Germany) at a rate of 50 kilometers, i. e., about 31 miles per hour. The car was an ordinary third class carriage in which the necessary arrangements had been made for electric propulsion.—Uhland's Wochenschrift.

The following extract from the Telephone Tariff at Stuttgart may interest our readers: Within the town limits, for a five minutes' conversation, 2½ cents; beyond these bounds, for the same time, 6 cents. The yearly subscription for one telephone line is $25 for distances less than three kilometers, and $6.25 extra for every two kilometers in addition.—Electrotechnische Rundschau.

An electric contribution box is the latest Connecticut invention, says the New York Tribune. The minister touches a button, and small silver cars, lined with velvet, visit each pew simultaneously, running on a slender rail back of each pew. Each car returns to a lock box at the pew entrance, and the deacons collect the receipts after the service. We cannot vouch for the item, however.

The electric tramway at Lausanne, Switzerland, is interesting in this respect that it runs up the steepest incline that is surmounted by any train or train depending on adhesion to the rails. The way from Place de la Riponne to La Ponthaise at one spot rises by 11·3 per cent. and in another by 8·2 per cent. The cars run at 6 kilometers per hour, and on one occasion a velocity of 12 to 13 kilometers per hour was reached.—Uhland's Wochenschrift.

The recently established electrical tramways in Cairo are a great success, and, notwithstanding the very low rates, which are sometimes less than two cents for a distance of three miles, they are being worked at a profit. The electric lighting is also being extended, and on account of the numerous overhead wires which are spreading in all directions, the government propose to issue rules which will have to be adhered to in all future installations.

The gold mines in Transvaal are supplied with electricity at a pressure of about 250 to 500 volts. Some of the mines are 20 to 25 miles from the dynamos, the force being transmitted by overhead lines. Every precaution is taken to provide against accidents. The voltage is reduced to the required level of about 190 volts by transformers. The total horse power transmitted is about 2,100; the charge is £45 per annum per horse power, i. e., much less than the cost of steam.—Electrotechnische Rundschau.

On the 31st of March of the current year a stock company was formed at Batavia (island of Java) for the construction and operation of an electric tramway system there. The capital amounts to 1,600,000 florins, i. e., about $800,000. The contract for building has been made with a German company. Two single track lines are first to be laid of together about 15½ kilometers length. On these there is to be one car for coolies and one for Europeans every ten minutes. According to the contract, the line is to be opened for traffic in May of next year.—Electrotechnische Rundschau.

A new method of obtaining light through the medium of electricity has recently been described by O. Schutt, of Germany. A spark from an induction coil is passed through a thin (capillary) tube, into the ends of which electrodes of copper or aluminum are inserted. The light produced is very brilliant, exceeding in this respect the light of the arc lamp. A great drawback is that the tubes wear out very rapidly, especially if very narrow; wider tubes give less intense light, and so do tubes from which the air has been partly exhausted. Owing to this rapid deterioration of the tubes, the discovery seems to have no practical value.—Uhland's Wochenschrift.

Perhaps in no other branch of technical industry is the use of electricity as a mechanical power so advantageous as in mining. In collieries the work is often carried on in many places, considerable distances apart, and no force can be so readily transmitted as electricity. Besides, in many cases, mountain rivers supply cheaply the required force for the production of electricity. In Europe and America, rock drilling, exploding, the transport of material, the pumping, ventilating and lighting of the plant, are done by such means. And recently the firm of Siemens & Halske, of Berlin, have laid a complete plant of this character in Tokio, Japan, and also in the Transvaal a similar one is in preparation, where four dynamo machines will work with a total horse power of 4,000; the current will be partly transmitted as far as twenty-eight miles.

More than twenty English railway companies have adopted a system of lighting the carriages by electricity, such that each van is quite independent of the rest of the train. On every carriage there is a dynamo and a storage battery so arranged that when one is at work the other is at rest. The dynamo is driven from the axle of the carriage, and is constructed so that the current is automatically kept uniform. At speeds less than 20 kilometers per hour the dynamo is at rest, and the storage battery only supplies the electricity. The conductor can switch off either one-half of the lamps or all. Each carriage has two lamps, in the first and second class carriages of 8 candle power each, in the third class carriages of 5 each. The additional weight of each apparatus is 4½ cwt.; the cost of installation, $250 per carriage.—Electrotechnische Rundschau.

MISCELLANEOUS NOTES.

The number of Hungarian patents issued in 1895 was 3,191. Hungarians received 615 patents, Germans 1,377, Austrians 656, Englishmen 144, Americans 136, and Frenchmen 128.—La Propriété Industrielle.

Among 1957 patents granted in Switzerland in 1896, only 603 were issued to Swiss citizens, Germans coming first with 689 patents. Frenchmen obtained 214 patents, Englishmen 131, Americans 92, and Austrians 80.—La Propriété Industrielle.

Attempts to free rancid cocoa fat from its unsavory constituents have successfully been made at Thann, in Alsace. The patented process consists in acting on the best cocoa fat with overheated steam, and then allowing it to cool hermetically cut off from contact with air, after the volatile products of the action are driven off.—Prometheus.

In Russia cotton spinning is the most important industry. In 1843 there were 3,500 spindles, each of which supplied some 33 pounds of cotton a year; now there are 5,000,000, and each produces more than double the amount formerly given. The material is supplied from the Caucasian Mountains and Asiatic Russia.—Uhland's Wochenschrift.

The name meerschaum, it appears, is derived from the word myrshen, which was used to designate the mineral at Brussa, in Asia Minor, where it used to be found plentifully. Meerschaum is a product of the decomposition of serpentine. It is, originally, a soft, claylike gray mass, which hardens to the well known white solid. Chemically, its composition is represented by the formula $Mg_2Si_3O_8.2H_2O$.—Prometheus.

There has been a considerable increase of stock companies in Germany, their number being at the present day 3,300. Of these 362 are banks, 127 insurance companies, 430 of the remainder are devoted to traffic and transportation. Foundries, mines and salt mines provide another 280 companies, and quarries 201. Porcelain manufacture is mostly private property, so only 13 companies of this branch exist.—Uhland's Wochenschrift.

For the measurement of very low temperatures, electricity is now usually called to aid. But if for any reason it is desired to use a fluid thermometer, which is to be practicable at the boiling point of atmospheric air (− 190° C.), the fluid best suitable is a mixture of hydrocarbons known as petroleum ether. This substance shows a remarkably strong contraction on cooling, at − 188° C. its volume is ⅘ of that at 0° C. and ⅔ of that at + 30°.—Stahl und Eisen.

Italy alone, to the present time, has adopted the 24 hour system for designating the time of the day. In Belgium it was to be introduced on the 1st of May, both for railways and for mail and shipping service. So far, the system seems to have met with little favor in Germany, but it is expected that there, too, a change will take place before very long. In France steps have been taken in that direction, and Switzerland is to adopt the new reckoning on May 1, 1898.—Uhland's Wochenschrift.

The province of Norrland, Sweden, which occupies nearly one-quarter of the whole realm, besides being covered with immense forests, is extremely rich in iron ores, which are as yet scarcely touched. The importance of these north Swedish mines is greatly increased by the fact that it is expected the iron ore of other origin which has come to the market plenteously so far will continue to do so for twenty years more only. After that time, the working of the Swedish mines may become a matter of necessity.—Uhland's Wochenschrift.

In spite of all efforts to increase the consumption of domestic coal in Germany, the importation of English coal is continually growing, being better and cheaper than any Continental produce. In 1895 England sent to Germany 80,000,000 cwt.; in 1896, 86,000,000. Of the additional 6,000,000 cwt., by far the greater part was burnt in Berlin. In the first two months of the current year the importation of English coal has gone back a little by some 800,000 cwt. In France, also, the importation of English coal has increased considerably.—Uhland's Wochenschrift.

A postal oddity is reported from Hanover. A merchant wished to send some circulars to a German customer in the form of cardboard rolls, and was greatly disgusted to find that they were rejected as printed matter, because their length exceeded the limit for German inland postage—45 centimeters. By parcel post they would have cost him some $625. But a way out of the difficulty was found. It appeared that the rules of the international postal union permitted a length of 75 centimeters. So the circulars were sent to Holland by express, and were then sent on from there at 4 cents apiece.—Uhland's Wochenschrift.

A new process for dyeing skins by the aid of electricity is described as follows: The skins to be treated are laid out on a zinc table, which serves as positive pole. Then the color which is desired to be imparted to them is poured on and is connected to the negative pole. The current passes and causes the color to pervade the skins. The process can also be modified and employed to trace designs on the surface by admitting the current (from the negative pole) by a copper plate which has been cut out in the design required. The parts covered by the plate show lighter coloring than the others, when the process is completed.—Prometheus.

A considerable amount of raw sugar used to be exported from Germany to England, where it was refined, and then further transported to the United States. Of late the export from England westward has decreased; the consequence being that more sugar has been exported to the United States from Germany and less to England. The exports from Germany to England, in 1892–96, are given below:

	Raw sugar.	Refined sugar.
1896	2,010,792	3,050,176
1895	3,156,401	3,231,814
1894	2,631,787	2,456,307
1893	2,519,147	2,106,625
1892	2,450,358	1,760,368

—Uhland's Wochenschrift.

THE ENGLISH MISSION TO HARRAR.

THE English mission, composed of Mr. Rennell Rodd, ambassador of the Queen of England, Colonel Wingate, attache of the Egyptian government, Count Gleichen, a relative of the Queen and attache of the minister of war, Lieutenant Cecil, Captain of the Horse Guard Bingham, Captain of the Engineers Swayne, representing the Indies, and Interpreter Speedy, made its entry into Harrar on the second of April, at half past nine o'clock. An escort of Indian lancers preceded and closed the procession. These lancers, of the garrison of Aden, were selected on account of their tall stature. The procession traversed the city between a row of Abyssinian soldiers.

After the official receptions a collation was served, and the mission, which had declined the offer of hospitality of Ras Makonnen, proceeded to establish its camp outside of the gate of Choa, at about half a mile from the city.

On the next day (April 3) Ras Makonnen visited the English camp and had a few minutes' conference with the different members. The mission returned the Ras' visit during the day, and continued its visits in beginning with the venerable French prelate, Mgr. Chauvin, Bishop of Harrar, and ending with one to the Russian mission of the Red Cross.

On the 4th of April the English mission assisted at the divine service of the Coptic rite, a ceremony at which likewise were present Ras Makonnen and Colonel de Maximoff, head of the Russian Red Cross mission.

A curious incident occurred at the moment at which the clergy presented the crucifix to be kissed by those present, and there was an instant of hesitation among the officiants when it became a question of presenting it to the English mission, which, according to the belief of the Abyssinians, was not composed of Christians. It became necessary to parley with the Ras, who gave orders to present the cross to it. The members of the mission kissed it devotedly, to the great astonishment of the assembled Abyssinians.

The mission now made its preparations for departure. It seemed to desire to hasten the moment of starting as much as possible, since the presence of Ras Makonnen inquieted it.

Upon the whole, it was an embassy and reception of politeness. As far as politics is concerned, the character of the Abyssinians is too well known to us to allow us to believe for an instant that they will lay aside the reserve that they have been able to preserve up to the present toward all the civilized nations that have thought it their duty to enter into relations with them.

Emperor Menelik II will doubtless receive Queen Victoria's ambassador handsomely, and will lend himself to all the exigences of the Abyssinian protocol in order to listen to explanations of the avowed purpose of the mission, and will reserve his reply. This will be a burial of the first part of the question, and everything will re-enter the primitive order after much ink has been spilled and much powder wasted on joyous salutes. Persuasion will have no more influence than threats upon the negro, who now feels himself strong enough to refuse to have any further discussion about anything that touches the independence of his people and the total integrity of his territory.

We present herewith a copy of a photograph of Serkis-Terzian sent on by M. Bavelaer, the explorer, now on a mission to Harrar. As this former Abyssinian chief played an important part in forcing the submission of Harrar to Menelik, the following notes concerning him will prove of interest in connection with the subject under consideration:

Serkis-Terzian, a native of Armenia, and endowed with an extremely adventurous character, went, when very young, to Abyssinia and entered the army of that country.

After traveling over Abyssinia in all directions, our hero finally stationed himself at Harrar during the year 1883 and witnessed the evacuation of this country by the Egyptians in 1885.

RAS MAKONNEN AWAITING THE ARRIVAL OF THE ENGLISH MISSION UPON THE SUMMIT OF AOU ISSIN.

At the time of the accession of Abdulley, emir of Harrar, the fact that he was a Christian submitted him to all the vexations of that tyrant and of Mussulman fanaticism, and it was with a feeling of unrestrained joy that he learned of the Choans' preparation for war.

After the defeat of Abdulley's troops by King Menelik II and the flight of the emir to Berbera, the truly active role of our adventurer began. Deputizing him with other notable men of Harrar to bring to him the submission of that city, Menelik confided to him the mission of taking possession of the latter in his name.

Followed by twenty resolute, picked men, he, without striking a blow, entered the city in which, but a few hours before, he had been treated as a pariah and constantly menaced with death.

After putting guards at the gates and disarming the latter's defenders, he placed small detachments in the different public buildings. The day following this exploit Menelik made a solemn entry into Harrar.

The king made a gift to Serkis of the territories of Noie and Cambodia and of the tributes that he received therefrom, and then took him to his court. A few months later he was appointed governor of Ginel-deissa, a very dangerous post at the epoch and one dreaded by the Abyssinians. Through a regime of terror and numerous expeditions he was enabled to submit the Somalis to the authority of the king, and extended the conquest of these territories as far as to Bijo Caboba. It was upon his return from one of these expeditions that the photograph reproduced herewith was taken.

Finally, tiring of this life of adventure, which would

RAS MAKONNEN ON HIS WAY TO THE PALACE TO AWAIT THE ENGLISH MISSION, ABYSSINIA.

delight a writer of romances, Serkis retired to Harrar in order to devote himself to commerce. It was through the intermedium of him in great part that Menelik's army was provided with the first rapid fire guns that permitted this monarch to extend his authority and assume the independence of his states.

Serkis is still carrying on the business of selling arms, to which he has added a well stocked bazar, the management of which he has confided to his brothers, whom his new fortune has enabled him to call to his assistance.†

At the time of the Armenian massacres he brought to Harrar, at his own expense, several Armenian families that had escaped the butchery, and also sent aid to the Armenian committee.

His repose seems to weigh upon him, however, and the adventurer is seen to awaken in him when, with legitimate pride, he is recounting to some one the number of his legendary exploits.

The fact that his life has often been threatened and that a price was once set upon his head by the English has robbed him of none of his somewhat savage joviality.—Le Monde Illustré.

THE FUTURE OF CENTRAL AMERICA.

By JOHN RICE CHANDLER, in the Iron Age.

FEW Americans realize that the shores of the several republics which constitute Central America are but an easy two or three days' steaming from our coasts. In fact, the everyday fruit steamers running between Puerto Barrios (Guatemala), Puerto Cortez (Honduras), Bluefields (Nicaragua) and Limon (Costa Rica), usually make the trip to New Orleans and Mobile in from four to five days and to New York in five to six.

If two other points were clearly understood—the climatic conditions and the so-called revolutions—a much larger proportion of our people would visit these republics, and, incidentally, good will and commerce would be enormously increased to mutual advantage.

As to the climate. That backbone of the country, the Andean chain, has determined the question of elevation, therefore of temperature. Although the whole land is within the tropics, all the central plateaus have an elevation of 2,500 to 6,000 ft., with a mild, temperate climate. The coasts, and the coasts only, as might have been expected, are hot and sultry, and in some places unhealthy. All the cities and large towns are located, with few exceptions, in the temperate regions.

With regard to uprisings. These republics for over fifty years were continually in the throes of revolution. Some twenty years ago things reached a crisis, and the people at large seem to have become convinced that nothing but ruin and death was to be obtained by the methods till then pursued. Since then uprisings have taken place, but they have seldom lasted over a few weeks, and, but for a few sensational correspondents, never resulted in any particular harm to life or property.

As year after year has gone by and the Central Americans have been placed in closer contact with the outside world, they have developed a great desire for advancement in every line of life, and have shown this practically by the rapidity with which they have come into line with modern nations. The telegraph, telephone, electric light and steam railways are all to be found in ordinary use in each and all of the five republics. Modern machinery is found in the factories, the sugar, coffee and tobacco plantations. In fact, except among the lowest stratum, the people have the ways and manners, the amusements and ambitions of Europeans.

So far, foreign immigration has been slow to appreciate the favorable conditions presented by these countries, but now that such countries as the Argentine Republic, Brazil and Uruguay are relatively well supplied with foreign population, Europe is looking toward Central America as a future receiver of her surplus population. And well they may, for eight-tenths of the land is temperate in climate, and no more valuable crops can be obtained in any country.

Although large tracts of land are already taken up with the cultivation of sugar, cacao, tobacco, rubber and coffee (the latter alone producing a yearly crop valued at upward of $40,000,000), there are still hundreds of thousands of acres of land waiting to be put under cultivation, just as good in every way as that now producing. Most of the East Indian spices and medicinal plants could easily be grown in these republics, with the result that, like our coffee and cacao, the finest grades and best prices would be obtained. Another source of wealth is tobacco; it is grown successfully in the sheltered sections of Zacapa and Cojutepeque, as well as in Honduras, but with careful cultivation, selection, and last, but not least, capital, a product in nearly every way equal to the Cuban weed could be produced in large quantities and on virgin soil. That is a thing which to-day is impossible in Cuba.

Capital would immediately bring more railroads. At present there are nine lines running or in construction, but the interior of all these five countries remains to be opened up. When the Guatemala Interoceanic and the Costa Rica Railroad from the Atlantic to the Pacific are finished, a great impetus to commerce will surely have been given, but these republics will still be quite as far from one another as they are to-day. A series of branch lines will be needed to ramify through the rich sections of the interior, and then a north and south line running from the Mexican border and tapping their railroad system at or near Tapachula; following the Pacific coast line, this railroad (already surveyed by order of the United States government) would traverse Guatemala, Salvador, a part of Honduras, Nicaragua and Costa Rica, finally joining the South American railway system at Panama.

Not only would such a line have great value from a commercial point of view, but it would be equally important from a political one. The interests of the five sections of Central America are naturally in the direction of political union. Their language (Spanish), customs, ideas, and traditions, constitutions and general laws, are the same, or at least very similar, throughout. What is most needed at present is frequent and rapid intercommunication from Guatemala on the north to Costa Rica on the south. This is the only way to bring about a universal feeling and desire among the masses for union. The experiment in this direction, now being made by Nicaragua, Honduras and Salvador, is certainly very laudable, but the people do not seem to take "La Republica Mayor," which they have formed, very seriously as yet. The sections are still too far away from one another to feel the benefit of such a union. But little can be done in this direction as long as it takes fifteen or even twenty days to travel from one section of the country to the other, as is now the case. Notwithstanding, the union of the five republics under the Central American flag is bound to come. The better classes are beginning to see the great advantage of running one government instead of five, with all the attendant expense. Furthermore, they see clearly that a country with upward of four million inhabitants would have greater respect shown it by the rest of the world than under the present arrangement. They clearly understand that a new country, with a stable, honest government, rich in raw material and already producing large crops of the most valuable staples, would have many more chances of attracting American and European capital as well as immigration of the better elements.

The Central Americans point with pride to their splendidly appointed coffee and sugar plantations, equipped with the very latest types of machinery, whether for drying, cleaning and hulling coffee or mills and pans for sugar.

All this is not a circumstance to what the number, size and equipment of plantations will be, once the republic of Central America is erected on a solid basis and Americans realize that they have such a land of promise but a couple of days' sail from their own shores.

Perhaps one of the most important, if not the greatest element in the bringing about of favorable conditions in these republics, is the building of the Nicaragua Canal by Americans. The real patriots among the Central Americans see that it needs the moral and financial backing of a great and friendly power to push such a gigantic work to a successful end. They, therefore, prefer a partnership with the leading republic of the world to any inducements held out to them by European monarchies. To those who still have doubts as to the great commercial value of the canal the perusal of the statistics got up by the British to show the trade and estimated traffic through the canal is recommended. The tonnage from the United States to Asia and the Pacific coast of Spanish America is placed at 1,300,000; that between American and South American ports and Europe, 500,000 tons; trade between Europe, Asia and Australia, 2,000,000 tons. Among other reasons that might be put forward to show American capitalists, manufacturers and merchants that the present is the very best time to interest themselves in Central America, notwithstanding the depression caused by the fluctuation in silver prices, is the one that, in contrast to several South American countries, business is not yet overdone; openings in nearly every line can be made with moderate capital to yield handsome profits. Of course, it stands to reason that such rich territory will not long go begging, once the world is fully alive to the fact that life and property are as safe there as in almost any other part of the world.

SERKIS-TERZIAN, EX-GOVERNOR OF GUELDEISSA.

HOW TO AVOID TAKING COLD.

THE fin de siècle toilet is not complete without rinsing the mouth and spraying the nasal passages and the throat with an antiseptic solution night and morning. By these means the upper air passages are kept in an antiseptic condition, unfavorable to the development of germs, and disease is prevented. G. Lemoine, in the Nord Med. (Jour. Am. Med. Assoc.), states that numbers of persons by these simple precautions have passed through the winter and rainy spring without once catching cold, although they had previously been extremely sensitive, and troubled with severe colds much of the time. He recommends to rinse the mouth with a glassful of fifty grammes Labarraque's solution mixed with one liter of water, or the following: Thymol, 0·50 gramme; alcohol, 20 grammes; water, 1 liter. With an ordinary toilet atomizer the nasal passages and upper part of the throat should be thoroughly sprayed with some solution like the following: Phenol-salyl, 0·50 gramme; chlorid of sodium, 3 grammes; distilled boiled water, 500 grammes. He adds that the teeth should be well brushed, and the fingers never put in the mouth or nose. A few menthol drops should be carried in the pocket and dissolved in the mouth occasionally. He concludes with the remark that a friend of his has always succeeded in breaking up a cold in the early stages, by taking during the first day four to six capsules or pills of essence of turpentine in addition

to the rinsing or gargling and spray, with a glass of purgative water the next day, followed in a few hours by 0·50 centigramme of quinine.

THE SURGICAL STATUS OF THE BICYCLE.

FOR twenty-five weeks during the wheeling season, the Buffalo Express has collected statistics of accidents occurring to bicycle riders in the streets of that city. Before quoting figures, some preliminary remarks may be in order to call attention to their general significance.

Cold blooded as it may seem, it is necessary for the surgeon, like the physician of any branch of practice, or like the man engaged in business of whatever kind, to inform himself as to the sources of his employment. It is not simply with regard to the fullness of his pocket book that the obstetrician notes the average number of births to each marriage, or that the surgeon is interested in the influence of steam railroads or of trolleys on his practice. As a matter of practical philanthropy, it is desirable that every one should anticipate, so far as possible, the demands which are likely to be made upon him, while sociologic questions are solved only as each worker notes the influence which the various institutions of civilized life have upon the welfare and detriment of the human race, so far as his own possibilities of observation extend.

The statistics gathered by the Buffalo Express ought to be fairly representative. The city is one of the second magnitude, having—exclusive of suburbs—about 350,000 inhabitants. One in seven of these, or about one in four, who may be expected to use the highways, ride bicycles, to some extent. Although supplied with over two hundred miles of smooth pavement, the majority of the riding, both by men and women, is for business and therefore on downtown streets. These are not so wide nor so empty as might be desired by cyclists, still there is no such crowding as occurs in New York and Boston, none of the tortuous and narrow streets of the latter and none of the bad pavements which still linger in Philadelphia. On the whole, the conditions are as favorable as can well be expected without being ideal.

The Express has chronicled, between April 15 and October 10, sixty-three bicycle accidents serious enough to involve medical attendance. The editorial writer also states that he personally knows of a number of cases that did not get into print and estimates the total number of accidents as about one hundred, or four per week. No deaths have resulted, although many of the injuries were, at first, thought to be fatal. The distribution of these accidents, so far as time is concerned, is about equal for May, June, August and the parts of April and October covered by the statistics. Five accidents occurred in July and sixteen in September. The increase for September is correctly ascribed to the greater amount of traffic. The minimum for July was probably due in part to the diminution of business, the absence of wheelmen from town and the relatively greater use of uptown and suburban streets. The Express explains an increase of accidents in May and June as probably due to the large number of novices riding, but the figures given do not show any such increase. Forty-one, about two-thirds of the cyclists injured, were men, indicating a relatively greater liability on the part of women. This is explained, not only by differences in dress and general physical development, which work to the detriment of the female sex, but by the common observation that women cyclists carry more bundles than men, and, therefore, have their wheels under less perfect control, and that they also take chances that none but the most reckless male riders would dare.

These statistics show in the most convincing manner that the popular notion as to the prevalent carelessness of cyclists is totally wrong. Only six serious accidents to pedestrians can be charged against 50,000 wheels in half a year, and it is more than possible that some of these six may have been partly, or wholly, due to carelessness of the injured persons. Moreover, of the sixty-three injured bicyclers, only five had suffered from collision with other cyclists, representing, probably, not more than three serious accidents, since apparently the figures refer to the number of injured persons and not to the number of collisions. In other words, these 50,000 cyclists, riding for half a year—and the half during which wheels are most used—threading their way in and out through crowded streets, sometimes in such swarms that one might count a hundred or two in walking a block, are responsible for only about ten collisions with serious results. Four riders collided with trolley cars and one or two each with telegraph and telephone poles, trolley posts, curb stones, lamp and sign posts, etc.

In contrast with these meager figures, we learn that twenty-five of the injured bicyclers had collided with vehicles drawn by horses. The figures lend color to the general opinion of wheelmen that many drivers of delivery wagons, moving vans and hacks not only do not do their share in trying to avoid collisions, but take a malicious pleasure in cramping suddenly on the wheelman or otherwise blocking him and letting him avoid disaster—if he can. Many of those who are not malicious are criminally careless.

It should also be noted that, in all probability, many of the cases in which bicyclers have run into poles and curbs are directly due to crowding by vehicles. In one such case—whether included in the list or not, we do not know—a wheelman was deliberately crowded to the curb by a hack driver and fell, sustaining a compound fracture of the leg.

We are not aware that there is any characteristic injury resulting from bicycle accidents. The rider is supported by feet, perineum and hands, so that no one part of the body suffers the entire force of impact. The direction of the collision, the rate of speed, the objects against which the wheelman falls, or against which he may be driven, his attitude on the wheel, all influence the lesion which he may suffer. It must be borne in mind, also, that a cyclist does not suffer one fall unless he is precipitated over an embankment or has some similar accident, but is pushed sideways by his momentum, after he strikes the ground, without being able to free himself from his wheel or to stand upright. Thus, he may sustain injuries to his knees, hands, shoulders or head, according to his efforts to save himself and according to the direction in which he stumbles. Those who do not ride bicycles, almost without exception, overlook the fact that the cyclist not only suffers the force of collision, but also the results of this pushing, stumbling fall.

The pedestrian often imagines that it is sport for the wheelman to run him down, and the comic papers have a large file of jokes to this general effect. The pedestrian, already on the ground, is struck by an air cushion, or is whirled out of the way by the fork or handle bar. The wheelman, on the other hand, bears the brunt of the collision on the perineum, and also receives a bad fall.

Much has been written on the dangers of wheeling, medical and traumatic, but we believe that actual statistics, as to the result of street accidents, are rare.—The Medical and Surgical Reporter.

REMARKABLE EXPLORATIONS IN BABYLONIA.

A CORRESPONDENT of the Times says that Mr. Haynes, who for nearly five years has been in charge of the American expedition excavating the great mounds of Nuffar, in Northern Babylonia, has unearthed the ruins of the oldest city in the world, the foundations of which were laid some six or seven thousand years before the Christian era.

The work was begun in 1888 by the University of Pennsylvania, the funds being provided by a small committee. The expeditions of 1888–90, under the direction of Dr. Peters, produced a harvest of about 10,000 tablets and inscribed objects, among them several records of Sargon I and his son Naram-Sin, whose date B. C. 3800 was by many regarded as the starting point of Babylonian history. Troubles among the Arabs and the usual difficulties with the Porte delayed the work for three years. In 1893 the explorations were renewed under the charge of Mr J. H. Haynes, and they have been carried on continuously ever since, and have produced results such as were never dreamt of even by the most ardent advocate of Babylonian explorations, and the history of civilization has been carried back to an antiquity never thought of. The methods of systematic research such as were employed by Curtius, Schliemann and Petrie, laying bare stratum after stratum of the ruined city, noting with care the position of every object, and above all the aid of photography, had never been applied until now. By this method the history of the excavated city may be read like a book, each stratum as it is uncovered furnishing us with a chapter of its long lost history. The story of Nippur as read in its ruins is indeed a remarkable one.

The great mounds of Nuffar are situated on the east bank of the now dry Shat-en-Nil, a great main artery navigation canal which once connected Babylon with the Persian Gulf. The central feature of the ruins is a vast conical mound, called by the Arabs Bint el Amir, "the Amir's daughter," which rises to a height of nearly 29 meters above the surrounding plain. This mound marks the site of the great ziggurat or temple stage tower first built by Ur-Gur, or Ur-Bahu, as he was formerly called, about B. C. 2800, and subsequently repaired and added to by later kings. This vast structure was the central point of the explorations by Mr. Haynes.

The arrangement of this temple and tower of Ur-Gur bears a most striking resemblance to the early Egyptian pyramids. At no period in early Chaldean history was there so close a contact between Egypt and Chaldea as during the dynasty of Ur-Gur Dungi and Gudea of Lagash. These rulers, as we know from their numerous inscriptions found at Tello by M. de Sarzec, were in constant communication with Egypt by sea and through the Sinaitic peninsula. It was from this region that they obtained the hard diorite and porphyry for their statues and door sockets. The statue of Gudea, seated and holding the plan of a temple on his knees, is most Egyptian in character, the attitude resembling that of statues of Khafra and Menkara; moreover, the scale engraved upon the tablet gives the Egyptian and not Chaldean cubit. The tower rests upon a massive platform of crude brick. Excavations conducted below this revealed the existence of a second pavement of much finer construction, being built of kiln-burnt bricks of great size—the dimensions being 50 cm. square and of great thickness. Nearly the whole of these bricks were inscribed, and bore the stamps of Sargon I and Naram-Sin, his son, and its date, therefore, is just a thousand years prior to the buildings of Ur-Gur—namely, B. C. 3800. From the inscriptions of both these kings we know that they both built large portions of an older temple of Mullil.

Northwest of the temple was a line of mounds marking a rampart, and Mr. Haynes in 1895 cleared a portion of it and unearthed one of the most extraordinary pieces of masonry ever discovered. The foundation consisted of a solid bed of clay mixed with straw and puddled down, resembling some of the constructions found by Dr. Schliemann at Hissarlik. Upon this foundation and plinth was constructed a solid brick wall, 52 feet in thickness and rising to an unknown height. The builder of this wall was Naram-Sin, whom so many have regarded as a mythical king. It is probable that this rampart formed also a broad roadway round the city, and it may possibly, as Mr. Haynes suggests, have had a row of chambers in its upper part. Directly southeast of the great tower and close to the great rampart Mr. Haynes discovered a chamber with no doorway—it was evidently a vault entered from above, and was built by Ur-Gur. This and a second chamber immediately below it were the archive chambers of the temple, which had been partly restored by Ur-Gur, while the second was that of the king, built up to the level of his own pavement.

It is clear that at some time between the time of Ur-Gur, B. C. 2800, and the rise of the Kassite dynasty, B. C. 2200, the archive chamber had been broken into and large numbers of objects carried away and the rest broken and scattered. There can be little doubt that this disaster took place during the terrible Elamite invasion in B. C. 2285, when all the principal temples were pillaged and their treasures carried to the Elamite capital. We have proof of this afforded by a small disk of agate found in the ruins, which bears on one side a dedication by Dungi to Mullil, and on the other a dedication by Barnaburyas, B. C. 1400, which states that it was taken from "the palace of Susa in the land of Elam." The amount of debris from the pavement of Naram-Sin to the top of the mound is 11 meters in height, and this, we know, took close on 4,000 years to accumulate. Mr. Haynes, encouraged by the success of his work in the upper stratum, proceeded to excavate to reach the virgin soil, which he did at the depth of 9·35 meters, passing through the debris of ruined buildings, accumulations of broken pottery, and fragments of inscribed stone objects and well constructed drains. These remains prove the existence of at least two temples below the pavement of Naram-Sin, which at the most rapid rate of debris accumulation cannot be assigned to a later date than between six and seven thousand years before the Christian era. This lowest stratum has been much disturbed and the buildings pillaged; still, sufficient remains to reveal to us earlier phases of Babylonian civilization than we have ever seen. The first structure discovered was an altar of sun dried bricks, 4 m. by 2·46. The upper course had a rim of bitumen, and upon the altar was a large deposit of white ashes. Round the altar was a low wall marking the sacred inclosure. Outside of this inclosure were found two immense vases of terra cotta. These great specimens of early pottery were each 63·5 cm. high and decorated with rope pattern. We have here in this simple, sacred precinct the germ from which sprang the great temples of Chaldea—the altar, with its temenos, entered only by the priest, and the two great vases for purification, replaced in after times by the greater and lesser absu, placed before the temples. A somewhat similar construction was discovered at Sippara, but its archæological value was not recognized. Southeast of the altar was found a remarkable structure, a brick platform, 7 m. square and 3·28 m. high, built of fine unbaked bricks. Round the base of this Mr. Haynes found a quantity of water vents, which indicated a connection with some receptacle below, and on sinking beneath this solid mass he found a drain passing underneath the platform, in the roof of which was the earliest known keystone arch. It is 71 cm. high and has a span 51 cm. The bricks are well baked and joined with stiff clay as mortar. Thus the priority of Chaldea in the use of the keystone arch is clearly established.

This structure was over 7 m. below the pavement of Ur-Gur and 4·57 below that of Naram-Sin, and, since there were no massive ziggurats or great temples to crumble into ruin, it must have taken many centuries to build up so great a mass of débris, and an estimate of from 1,500 to 2,000 years before the time of Sargon does not seem too high.

Over 26,000 tablets as well as numerous inscribed fragments of vases and stelæ have been recovered from this site. It is therefore clear we have no lack of material. Under a pavement of Ur-Ninip, a king of the dynasty of Ur-Gur, were found some hundreds of broken vases and other objects that had been votive offerings to the shrines of Mullil from the earliest times. Among these were some of the most archaic type, and Professor Hilprecht, almost at the loss of his eyesight, has constructed a complete text of 132 lines written in a most archaic character. These records relate to a series of primitive wars and form certainly, whatever their age may be, the oldest historical records known. The earliest of these is the inscription of "Eshagsagana," styled "lord of Kengi," that is, Lower Babylonia, in whose time the chief enemy of Babylonia was the city of Kish, the modern El Hymer, whose priest ruler had entered into alliance with some fierce tribes called "the hosts of the Land of the Bow." The first inscription describes how the Babylonians "conquered the king of Kish and his ally," and spoiled his city. The next inscription is one of the king of "hordes of the bow" who had had his revenge and conquered Babylonia. The conqueror describes his empire as extending from the Lower Sea of the Tigris and Euphrates to the Upper Sea (Mediterranean), and as being granted dominion over all lands from the rising to the setting of the sun, whom he has caused to dwell in peace.

Who were the "hordes of the land of the bow"? Professor Hilprecht has put forward a theory that they are to be identified with the Semitic tribes of North Mesopotamia, and that the "City of the Bow" was Harran. It is rather (our correspondent says) to the plains of Central Mesopotamia and the lowlands between the Tigris and the Kurdish mountains that we must look for the home of these nomadic warriors.

This exploration reflects much credit on its organizers and, above all, on Mr. Haynes. For thirty-two months he lived alone among the wildest Arab tribes in Mesopotamia, in an atmosphere of fever varied with cholera. One determined attempt was made upon his life; yet amid all these surroundings he lived and did the work of three men. He is entitled to a place in the front rank of explorers along with those who have restored to us the first chapters of the world's history.

DRIVING OSTRICHES.

POTCHEFSTROOM, or Mooi River Dorp, was the second seat of government of the Transvaal, the first having been Origstadt, which, being in the low bush country, was first decimated by fever and then deserted; from Potchefstroom the seat of government was removed to Pretoria. It was an out-of-the-way place, and was seldom visited by English, except by hunters and traders on their way to the Zambesi, Lake Ngami and the Matabele and Bamanwato countries, and in the colonies it was very rare to come across any one who had been there. On our way back we purchased at a farm four young ostriches, a few months old, and not quite half grown. We had considerable difficulty in getting them off the farm. A little further we bought three more, a little older and three parts grown, and these gave us proper work to get them away. For a whole day we were chasing them all over the country on foot, for we had brought no horses, not anticipating this kind of work; but they always returned to the house, and toward evening we gave it up. In the morning at daybreak we spanned or hobbled them with silk handkerchiefs, and in this way managed to get them six or seven miles from the farm.

The next day we removed the handkerchiefs, as they were injuring the birds' legs, and for a little while they went along quietly, until they sighted a troop of wildebeestes, when they stretched out their necks and were off at their best pace to join them. We then each seized one of the two wagon whips we had and started after them. If the birds had been real wild ones and full grown we might as well have

started after an express train, for I never sat the horse that could run down a full grown ostrich in a fair course; but they were only three parts grown, and had been domesticated on a farm since they came out of the egg, and they were really more indulging in gambols than making a serious attempt to join the wildebeestes. Consequently, we succeeded in driving them back, but the performance was repeated fifty times during the day, and we had not a moment's rest the whole day. It was quite dark when we at length arrived at the river, and but for the assistance of the rest, who came to our aid, we should never have got them through. At camp we threw ourselves exhausted on the ground, and both declared that it was by far the hardest day's work we had ever done in our lives. The distance we had run after those wretched birds was certainly over fifty miles, and for the greater part of the distance we were cracking heavy wagon whips as well.

These ostriches were afterward a source of endless trouble to us. They grew rapidly, and developed great kicking powers, until they became sometimes positively dangerous, the dogs and the Kafirs coming in for most of their attentions. Their appetite was insatiable; we used to make large quantities of biltong, or sun-dried meat, and there were usually dozens of strips of it hanging on rheims slung from wagon to wagon, and these were always objects of attention on the part of the ostriches. It was most amusing to see one trying to swallow a strip a yard long and two inches thick, just as a chicken struggles with a worm that is a little too big for it. Once we had to drag a huge strip out of one of the birds' throats to save it from choking. But it was the culinary department that interested them most. They would always attack the Kafirs bringing the viands from the "kitchen" to the tent, and sometimes were so pertinacious that the boy would get frightened and throw the dish away and bolt, and we would lose the best part of our dinner. They would even come into the tent and snatch things off the table, and we would take it out of them by smothering a dainty morsel with salt and cayenne pepper; but after a while they seemed to flourish on it. One day, however, we got the laugh on our side. Dinner was preparing, and one of the birds was investigating the pots round the fire; a great pot of huge potatoes took his fancy, and he incontinently seized and swallowed a red hot tuber as big as a large pomegranate. He danced, he jumped, he kicked, he twisted his neck about almost into knots, he flopped his wings and waggled his tail, he ran amuck, knocking things down and banging himself up against the wagons and stone walls, and at last tore away into the veld at twenty miles an hour, until he was out of sight, and did not appear again for a couple of hours.

Every morning, soon after sunrise, these birds would indulge in a dance. They would rush away into the veld for about a mile, and then suddenly stop and commence waltzing round and round in the most ridiculous fashion, often till they dropped. I never could understand the meaning of this performance; it might be mere gamboling, but if so it must be nearly the only case of young birds playing, as so many young animals do. Their keen sense of sight has often been noticed, but it is not generally known that their sense of hearing is quite as acute, and if they were feeding two or three miles away, a few mealies (maize) rattled in a tin pannikin would suffice to bring them back.—South Africa.

THE INTELLIGENCE OF ANTS.

To the Editor of the SCIENTIFIC AMERICAN:

I have often thought that some of the conclusions advanced by Sir John Lubbock in his great work, "Ants, Bees, and Wasps," were, to a certain extent, erroneous. Furthermore, I believe that these faulty deductions on the part of this observer were the result of the unnaturalness and the artificiality of his experiments.

In almost every experiment conducted by Sir John, and detailed in the book referred to above, the ants used were placed amid artificial and specially prepared apparatus; hence, amid new surroundings with which they were utterly unfamiliar.

When we take into consideration the fact that, to an ant, in all probability, every stalk of grass is a forest tree, every bowlder a high and lofty mountain, and every minute crack or crevice in the ground a crevasse or abyss of appalling depth, we will readily comprehend the fact that, when they are transported any distance from the nest and placed among unfamiliar scenes, they must necessarily be handicapped by a perfectly natural bewilderment. Man himself, with all of his vaunted intelligence, would find himself at a loss under like conditions. When studying the psychology of the lower animals, they should be observed, I take it, among natural conditions; experimentation should be as inartificial as possible.

Ants soon arrive at a thorough knowledge of the country surrounding their nests; they very soon become familiar with the "lay of the land" over which they range. Hence, in the following experiments and observations, I have observed the ant at home; I have not placed an additional and unfair burden upon her intelligence by transporting her to a foreign country amid unknown scenes. Furthermore, I have not taxed her ratiocinative powers beyond their physio-psychological limits, as was done in more than one of Lubbock's experiments.

In front of my house there is a paved walk ten feet broad and three hundred feet long. Beneath the bricks of this pavement are the homes of several species of ants. These ants were the subjects of my experimentations, and this pavement was the place where the experiments were made.

In summing up his observations on the extent to which vision aids ants in finding their way, Lubbock says that ants, at least the species (Lasius niger) experimented with by him, guide themselves but little, if at all, by sight. I am convinced that this is an error; an error engendered, first, by the unnecessary artificiality of his experiments; second, by his ignoring the limit of the range of vision in L. niger.

Two larvæ or grubs of L. niger were placed on a nickel five cent piece some ten inches from the nest and a marked ant put to them. She examined them carefully, then, picking up one, she carried it to the nest. While she was absent, I placed another grub on the coin. She soon returned and again carried a larvæ into the nest. While she was absent on her second trip, I moved the coin and larvæ some eight inches to the right. When she returned, she passed over the original spot, then circled about as though looking for the desired object; finally, after several minutes' search, she entered the nest without having found the coin.

I performed this experiment repeatedly, gradually lessening the distance between the two points until I arrived at the distance of 1 in. between the spot made familiar to the ants by repeated visits and the point to which the larvæ were removed while the ants were absent. The ants seemed to be able to see the coin and larvæ at this distance, for they went to them at once, as soon as they discovered that they were not at the accustomed place.

This experiment was repeated time and again, always with a like result. At any distance over 1 in., however, the ants appeared nonplussed, and immediately began to hunt here and there for the coin and grubs. I believe that I do not claim too much when I assert that the ants were able to recognize these objects, at least at the distance of an inch. Moreover, I had reason to believe that their range of vision extended even farther, for on several occasions I had seen them turn and flee when they had unwittingly strayed within two or three inches of a "devil's race horse" (Phasmomantis carolina). I therefore tested their vision for greater distances in the following experiments:

I put several larvæ on a pillar 4 in. high and 2 in. thick. This I placed some distance from the nest, and, after I had accustomed a marked ant to the road between the pillar and the nest, I moved the former and stationed it some 10 in. away. The ants were unable to see it at this distance, but when the interval had been reduced to 2½ in., they found the pillar without difficulty. Experiments with larger objects, at greater distances, amounted to nil. Hence, I think that the extreme range of vision in L. niger approximates 3 in.

In order to determine whether or not smell was absolutely necessary in finding their way, I proceeded as follows:

Between the pillar and the nest (and thereby bridging one of the sulci between the bricks) I placed a piece of writing paper, 2 in. long and 1 in. broad; this bridge was directly in the ant's established pathway. When the ant arrived at the paper, she stopped, then turned and retraced her path several inches toward the nest; she again turned, walked across the paper and made her way to the pillar. When she first arrived at the paper, she evidently recognized the fact that here was something new and unknown in her path; bewildered for the moment, she turned and went back; finally, however, her sense of direction triumphed—she knew that the pillar was in a certain direction and that that direction was beyond the paper, so she traversed the bridge and went on her way to the pillar. It is hardly possible, nay, I believe that it is impossible, that she smelled out her route through the paper; indeed, I noticed that she followed the edge of the paper at least a half inch away from her old route.

Lubbock made an ant pass between several wooden blocks on her way to and from some food; he then changed the direction of the blocks until the space between them was tangential to the old route. Yet the ant invariably followed her accustomed path without noticing the blocks. He gives this as evidence substantiating his claim that ants are not guided by sight. I do not think that this is a fair conclusion. Suppose a man follows the footprints of another man through a lane which has a fence on each side; suppose these fences are changed during the night so that they will run tangential to their old site; must the man traverse the space between the fences if he desires to again follow the footprints?

I believe that the microscopic eyesight of the ant seizes on objects immediately at her feet—objects so infinitesimally minute that we have no cognizance of them at all. I believe that it is by such landmarks that she marks out and recognizes her route to and from any point. Of course, that most wonderful sense, the sense of direction (which all animals, save man, possess in some degree), has a great deal to do with the guidance of ants, but not all, by any manner of means. Even blind ants follow corridors, passageways and tunnels, hence it would seem that touch, and not smell, was the guiding sense, at least in blind species.

Again, in order to further investigate this question, I made a company of ants pass over a paper bridge on their way to a pile of bread crumbs. After the route had been well established and the ants had been passing to and fro over the paper for some time, I removed the bridge and placed it across another line of march which had been established by another company of ants which was busily engaged in carrying some larvæ into the nest. The paper bridge was placed athwart the line of the larvæ carriers, yet these latter did not appear to notice the trail of their companions on the paper, but crossed it at a right angle and passed on to the larvæ or to the nest.

Lubbock's experiments are always exceedingly elaborate, and it is this very quality of elaborateness which, in my opinion, very frequently militates against a correct result. He is rather disposed to question the often repeated and well authenticated statement that ants disinter comrades which have been accidentally buried, simply because, in his highly artificial experiments, they failed so to do.

Probably, if he had dispensed with his intricate and elaborate apparatus, consisting of "a vessel containing honey, which vessel rested in another containing water; a shallow box containing powdered earth; a paper bridge, etc.," and had experimented, naturally and inartificially, with ants which were at home and amid well known and familiar surroundings, his results would have been different. Moreover, in his experiments, he expected the ants to solve problems which man, with all of his intelligence, would find absolutely and entirely beyond his powers.

He accustomed some ants to cross a box of powdered earth on their way to a vessel of honey; after they had learned the route, he buried several of them in the powdered earth. "At 7 A. M., the next morning, the honey was all gone, two or three were wandering about, but no notice had been taken of the prisoners, whom he then let out."

Suppose a company of desperadoes seized a man and buried him in the middle of the public highway; suppose, also, that no one saw this burial save those who committed the outrage, that it was utterly unknown; is it at all probable that passersby on that highway would discover that a man was buried in the road? And yet, Sir John expected his ants to solve just such a problem!

That ants, on occasions, do disinter buried comrades cannot be questioned. Whether or not they are influenced by affection and pity to render aid to their hapless kindred, I know not; yet the fact remains that they do.

Seating myself beside a nest of Lasius flavus, I noticed that numerous small workers were bringing up the earth and depositing it in a circle about the entrance. Several large workers were walking about, seemingly directing the small workers where to lay down their loads. Seizing my opportunity, I suddenly buried three small workers beneath a pinch of sand. The large workers immediately hurried into the nest, from which, in a few seconds' time, there issued a crowd of small workers which at once began to remove the sand. In a very few moments the buried ants were disinterred, and were then carefully cleaned by the tongues of their rescuers!

In this experiment I endeavored to imitate a natural phenomenon. I produced a catastrophe, which, doubtless, frequently occurs to ants in a state of nature. A sudden and violent gust of wind or the busy feet of some industrious fowl have, unquestionably, often brought about just such miniature avalanches of sand.

Again, I glued an ant by one leg to a brick with some quick-drying cement. The struggling creature was soon discovered by some of her sisters, which at once began to free her by eating the glue about her feet. They quickly set her at liberty, but did not abandon her until they had thoroughly cleansed her. Thinking that, probably, they were influenced by a personal motive, i. e., that they ate the glue because they liked it, I mixed some quinine with it and then fastened another ant to the brick. She was soon surrounded by several comrades. I saw them bite the glue and then step aside and endeavor to rid their lips and tongues of the objectionably tasting substance. They returned, however, to their task, nor did they cease until they had freed the prisoner and had thoroughly purified her.

This seemed like true, disinterested pity and affection, especially since some of the ants were made sick by the quinine. I am fully aware of the fact that many observers have attributed a certain degree of emotional æstheticism to ants; yet it would be exceedingly difficult to prove that any element of æstheticism enters into the pity, sympathy or affection that these creatures may entertain for one another. Their interests are so entirely communal that individualism (the communal mother and, sometimes, the communal father being excepted) is entirely unknown; hence, any interest evinced by an ant toward another ant must be, necessarily and fundamentally, selfish in its nature. Incidentally it is for the good of the individual, but primarily and principally it is for the good of the colony, inasmuch as each individual is a fraction of the integer, which would be, to a certain extent, marred by the loss of a single ant!

That ants do evince a material interest in one another cannot be disputed; and such is their status in the economy of nature, that it is well for them, perhaps, that this interest is material instead of æsthetic.

On one occasion I disabled a rufous ant by amputating two of her legs. I then placed her near the entrance to her nest. An ant came out and, after examining her critically, took her up and carried her into the nest. Lubbock gives an instance of ants nursing and caring for a sick comrade. McCook, Forel, Huber, Belt, Bates, and many other observers also give instances of ants caring for and assisting wounded or sick comrades; therefore, I think that we may accept it as a fact. Yet Lubbock seems to infer from his bottle experiment that ants do not assist one another when in difficulty. He put some ants in a bottle, over the mouth of which he tied a piece of thin muslin. These imprisoned ants were visited by their friends, yet no effort was made to liberate them.

If a glass wall reached from the equator to the zenith and encircled the entire earth, thus separating the inhabitants of the world, the people on the north side of the wall, I take it, would consider themselves just as free as those who dwelt on the south side of it. The ants, in Lubbock's experiment, reasoned pretty much in the same way. The ants in the bottle did not know that they were imprisoned, nor were the ants on the outside any wiser. The experimenter ignored the physio-psychical limitations of the animals under observation. If, in his experiment, he had made the ants cognizant of the fact that their friends were imprisoned, they would have endeavored to free them; of this I have not the slightest doubt.

The tender and watchful care that is bestowed on the young ants by their foster mothers is exceedingly striking. In fact, were it not for these watchful guardians, the young imagoes would die in infancy, for the young ants cannot emerge from their cocoons unaided; they will die as pseudo-crysalides unless the old ants assist them to come out.

The education of the young takes place in the darkness of the nest, and they are put to work early in life. In point of fact, I have seen the young of rufous ants, only six hours old, busily engaged in caring for pupæ which were about to emerge from their cocoons.

It was my fortunate privilege very recently (May 22) to witness a sight not vouchsafed to many observers. In fact, I can find nowhere recorded a like instance. So it probably stands unique in the history of ants. I was observing a colony of yellow ants (L. flavus) when a dozen or two large-headed individuals came out of the nest and carefully quartered the ground to and fro in its vicinity. They seemed to be a scouting party sent out for the purpose of seeing if there were any enemies in the neighborhood. After they had examined the ground for several feet on all sides of the nest, they came back and stationed themselves about the entrance. In a few moments a large number of young ants came out accompanied by a number of ordinary workers. The large-headed ants formed a circle about the entrance of the nest and kept the young ones from straying away. These latter, apparently, were out for exercise or play, for they raced about, wrestled with one another, and indulged in mimic battles. The

workers walked about among them for all the world like monitors or ushers in charge of a company of school boys. This strange scene lasted for fully two hours; the young ants then gradually went into the nest, followed by the workers; finally the large-headed individuals disappeared and this astounding show came to an end. I called my gardener to witness this unique performance, but I must confess that he disappointed me by saying that he saw "nothing at all wonderful in the affair."

Several observers have stated that they have seen ants at play, but none of them have recorded the fact that they have ever seen young ants engaged in any such performance as I witnessed.

JAMES WEIR, JR., M.D.

ANIMAL COLONIES AND THE FORMATION OF ORGANISMS.

LAMARCK was the first to assert that, although the origin of life still remains mysterious, scientists should not consider the mystery as impenetrable. Life must have appeared upon the earth under the action of forces that are still acting, but that we do not know how to combine, and the illustrious naturalist endeavored, as far as it was possible in his time, to ascertain how the miracle of such appearance had been performed. Supposing this problem (which we ourselves will doubtless have to relegate to the scientists of the next century) to be solved, and recognizing the fact that there are simple and complicated animals, he was naturally led to ask if the latter did result from an improvement of the former. It seems to him that the organism of living beings must have varied by very reason of the variety of the terrestrial world. Two similar animals, placed in different conditions, must, according to him, have experienced different needs, and, in order to satisfy these, must have used their organs differently. The same organs, left in repose by one and put in activity by the other, must have become atrophied in the first and become developed in the second. At the end of a certain length of time, these animals, primitively alike, must therefore have become different. The variations thus acquired by exercise or disease of the organs must have been transmitted by heredity. Hence the diversity of living forms.

Unfortunately, although Lamarck succeeded in plausibly explaining the modifications of organs that already exist, their adaptation to different uses, or even their disappearance in consequence of their inertia, he was able, as regards the appearance of new organs, to make suppositions only that were so hazardous that they caused his powerful conception to be momentarily forgotten.

Lamarck's theory, being based upon the existence of a sensation, that of need, which in turn brought in the intervention of a faculty essentially animal, that of will, was, moreover, inapplicable to plants. Although it permitted of understanding in a certain measure that the animal organism had been the subject of gradual and continuous modifications, it took no account of one indisputable fact common to the two kingdoms—the existence of species, that is to say, of forms which, even when they are allied, as the dog, wolf and fox, the rabbit and the hare, or our little singing birds, can live side by side without intermixing and without any transition ever being found between them.

It is just this aspect of the question that Darwin examines. Leaving aside the question of the origin of living forms, taking them at any degree of complication whatever, and even abstaining from trying to ascertain under what influences such forms become modified, Darwin borrows his starting point from Lamarck—the heredity of characters acquired during life in any manner whatever. He then shows how, the hereditary variations having been once acquired, the multiplication of similar but not identical living beings in the same region involves a struggle for existence, in consequence of which those beings alone that possess the most advantageous characters under given conditions succeed in living for a long time and in reproducing themselves. Such survival of the fittest has for counterpart the disappearance of the less favored. So the advantageous variations exalt themselves from generation to generation. Every useful variation is soon carried to its maximum of intensity in some individuals, and the latter hence cause the disappearance of all those that come in late behind them. The chain of variation that connected the individuals existing at their starting point is thus broken, and a new species, entirely isolated in appearance, has been created. What Darwin has endeavored thus to explain is therefore indeed, as the title of his book shows, the Origin of the Species. What Lamarck proposed was an entirely different problem, that of the origin of variations in animal forms. The solutions that the two proposed leave out a third problem, that of the formation of organisms and of the causes that have led to their gradual complication.

I have endeavored to broach this third problem in a book that I have published under the title of "The Animal Colonies and the Formation of Organisms." The conditions under which it is proposed are now very plain. All the micrographic studies to which innumerable naturalists have been devoting themselves for more than sixty years past, and that have now attained the utmost precision, lead to the formulation of the following proposition: All living beings easily visible to the naked eye are formed through the agglomeration, in quantities that are often innumerable, of microscopic elements of quite complex but constant structure, differing from each other only in secondary details of form, and which are named indifferently "anatomical elements" or "plastids."

On the contrary, the majority of the microscopic living beings are formed of a single plastid capable of multiplying itself by division, and the plastids that emanate one from another in this way rapidly cease to exhibit any tie between them. These beings formed from a single plastid (Fig. 1) constitute a large group in the animal kingdom, that of the Protozoa, of which the infusoria are the best known representatives. In the vegetable kingdom they are the simplest of the fungi and algæ. The microbes and bacteria are examples of the latter that have now become familiar.

On another hand, however varied be the phenomena of multiplication in the organisms formed by an association of plastids, in the vegetable as well as in the animal kingdom, the pluricellular organisms always have for a starting point a single plastid, the egg, and the innumerable plastids that concur in the formation of the body of a high organism are all, without exception, derived from the repeated divisions of this primitive plastid.

Since in the present world every individual begins by being reduced to a single plastid, and since there still exist in our day a large number of beings that remain reduced to such state, it is natural to conclude that the first living beings were all unicellular, and that, consequently, the original ancestors of animals entered into the great category of Protozoa. This conclusion will assume considerable force if there still exist series that rise without too abrupt starts from the Protozoa to the most complex forms of the animal kingdom. Further along the question will be proposed whether such forms have been created all at once or

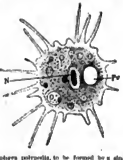

FIG. 1.—Dactylosphæra polypodia, to be formed by a single plastid, the substance of which is drawn out in threads temporarily. (Highly magnified.) N, nucleus that presides in the nutrition of the plastid; Pv, vesicle that expels waste material of nutrition.

whether they have been produced by successive stages, and whether it is not possible to recognize in the realization of such stages the constant exercise of some faculty common to living beings. Such faculty once known, the proximate cause of the complication of organisms would be by that very fact determined, and we should have to endeavor to ascend from this cause to others that are more profound.

Now, an attentive study of the animal kingdom shows that all the pluricellular organisms that compose it allow themselves to be easily grouped in five series:

1. SPONGES (Calcareous sponges and Siliceo-corneous sponges).

2. POLYPS (Hydromedusæ, Siphonophoræ, Acalephæ, Ctenophoræ, Coralliaria).

3. ECHINODERMS (Cystoids, Blastoids, Asteroids, Ophiuroids, Echinoids, Holothuroids, Crinoids).

4. CHITINOPHORÆ (Arthropods: Onychophoræ, Merostomæ, Arachnida, Pycnogonidæ, Crustacea, Myriapods, Insects; Nemathelminthes: Echinoderidæ, Acanthocephala, Gordiacidæ, Desmoscolecidæ, Nematoids).

5. NEPHRIDIÆ (Lophostomæ: Rotifers, Bryozoans, Brachiopods; Worms, Mollusks, Tunicates, Vertebrates).

In each of these series the organisms may be arranged according to an order of increasing complication, from a simple form in which we observe no other repetition of parts than that of the plastids (which, moreover, are apt to group themselves into dissimilar organs) up to diversely complicated forms whose body divides in most cases into parts that are more or less similar, and in which all the organs are repeated. Each of the parts into which the complex forms are decomposed has, moreover, exactly the same structure as the form with which the series begins. It is, therefore, possible to connect all the organic forms comprised in a same series of the animal kingdom by a simple law: The complex forms of a given organic series of the animal kingdom are only an aggregate of parts identical with the simplest form of such series. It is to aggregates of this kind that naturalists have given the name of colonies.

In the presence of this general proposition, we may give a name to the initial form of each series, and we shall call it a merid. We shall designate the complex forms as zooids. A zooid will, therefore, be a sum of merids, just as a merid is a sum of plastids.

In the most complex organisms, the body is not solely divided into merids. We quite often distinguish therein groups of merids that assume a more or less marked individuality and may even separate from the zooid in order to lead an independent existence. Each of these groups must be considered as a zooid. The entire organism is, therefore, either a sum of merids and zooids or a sum of zooids, that is to say, something more complex than a zooid. The organisms thus constituted we shall call demes. A simple law still further connects the zooids and demes in the same series: In each series of the animal kingdom the lowest forms are merids. Afterward come the forms constituted by the repetition of merids all alike, and which are, consequently, zooids. Finally come the forms constituted by a sum of zooids that are in general different from each other, and that, consequently, have the signification of demes.

Thus, the plastids do not seem destined to constitute an organism all at once. Just as men do not form, all at once, great nations that are centralized to such a point as to be but a single body of which all the parts are harmoniously founded, just so the plastids unite feebly in the first place (Fig. 2), and then become aggregated into merids, which afterward become aggregated into zooids, that in turn form demes. Just as the ties that connect the tribes of the same people, and the cities and provinces of the same nation, are in the first place quite lax, but become closer in measure as the relations become easier and the common interests become more numerous, just so the merids and the zooids, which might at first easily separate from each other in order to lead an independent existence, become more and more thoroughly independent and finally become no longer separable.

The instrument of such solidarization is the same in both cases. In human societies, progress is due to the variety of aptitudes combined with individual initiative. Every happy initiative assures advantages to those who have taken it, and of these they have doubtless the exclusive benefit for a certain length of time; but their prosperity soon becomes an advantage to the family and to the people of which they form part. Such initiatives are exercised in different directions, by very reason of the variety of the faculties of the individuals. It soon results that each assumes a role that is adapted to him in the society of which he forms part, and such division of roles between the initiators is what is called a "division of labor." As the labor of each is profitable to all, and as each one works according to his aptitudes, if a sufficient initiative is left to him, and consequently works better than if a task for which he is not fitted is imposed upon him, and as every laborer does so much the more perfect work in proportion as he devotes himself thereto more exclusively, the division of labor leads to the consequence that a relatively limited number of individuals have in charge the production of the objects that are indispensable to all. From this moment, all the producers become reciprocally necessary, and a close interdependence is established between them. They become thereafter inseparable from one another, and the society to which they belong acquires by that fact all the characters of an individuality of a high order. The role that each individual played voluntarily becomes a social function.

The function, moreover, impresses upon those who exclusively exercise it special external characters that permit of the recognition, with some precision (by a practiced eye, at least), of the soldier, the priest, the magistrate, and the laborer, and, among the laborers, the corps of trades often have a certain manner which, even in the absence of any special costume, clearly betrays them. The division of labor, while inducing solidarity, therefore induces a sort of polymorphism of the individuals. The individuals who perform the same function, or similar functions, whence they derive their origin, necessarily have interests in common. Peculiar ties are established between them and through their union they form corporations or syndicates that also possess a certain individuality, but a subordinate one, since it represents simply a function that would no longer have a reason to exist if the social body disappeared.

The unity of the social body, its solidarity, is, moreover, reinforced by the advent of real ties that put all its parts in intellectual communication, as do correspondence, newspapers and books. The organs of these material ties, by the very fact that they are designed to establish relations between all the parts of the social organism, are essentially, at the bottom, undivided properties, so that they may be momentarily exploited by private individuals. It is clear that the degree of improvement and development of undivided properties measures the degree of solidarity of the social body to which they belong.

All these things are evident, even from a superficial study of human societies. So, some physiologists, struck by the resemblances to animal organisms that such societies exhibit, have endeavored to deduce laws of political economy, those of the progress of organization, while politicians or philosophers, reversing the problem, have sought for comparisons suitable to sustain their conceptions in the history of the progress of animal organization. The problem thus reversed is evidently alone proposed in a scientific manner. It is rightly that Messrs. Espinas, Izoulet and Worms see in our human societies the last actual term of an evolution that has gone on through the entire animal kingdom. Hence an exact knowledge of the conditions and laws of this evolution assumes a philosophic importance of the first order, since such conditions and such laws, well understood, determine the place of man in nature and teach him his rights and his duties, not only with respect to his similars, but also with respect to all that surrounds him, living beings or inanimate objects. They are the sole bases upon which, in a society that asserts itself eminently laical, can be built a general

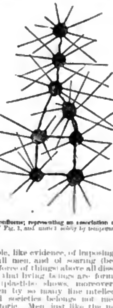

FIG. 2.—Monobia confluens; representing an association of plastids analogous to that of Fig. 1, and united solely by temporary prolongations of their bodies.

morality capable, like evidence, of imposing itself upon the minds of all men, and of soaring (because it results from the force of things) above all dissensions.

The sole fact that living beings are formed of individual units (plastids) shows, moreover, that the parallelism seen by so many fine intellects between organisms and societies belongs not merely to the domain of rhetoric. Men, just like the most humble plastids, are subjected to the triple necessity of feeding themselves, of assuring their individual security and of multiplying. The societies of the one, like those of the other, have no other object than that of being able to provide for this triple necessity by the most appropriate means. From the identity of object result resemblances that are so much the less debatable in proportion as the means employed to this effect are governed by the same conditions in general that form

what we call life. It is therefore useful, by taking a well defined example, to state with precision the successive stages of the organic complication in a determinate series, and we shall select that of the polyps as presenting the clearest phenomena.

Here the initial merid, which it is easy for everyone to observe, and which has been rendered celebrated by Trembley's experiments, is the fresh water hydra. This animal is a sort of cornet fixed by its closed extremity to walls formed of two superposed layers of plastids and with an aperture surrounded by hollow flexible prolongations called tentacles. The best fed hydra does not exceed a centimeter in length. As soon as it has reached this size it, instead of continuing to grow, produces a protuberance at some point or other of its body. This protuberance, which, as in plants, is called a bud, soon becomes a hydra similar to the first. The young hydra detaches itself before long and begins to lead an independent life. This phenomenon occurs during the entire summer; but in the autumn the animal produces eggs, which in the spring give birth to a new hydra.

The hydra, therefore, lives in the state of a merid. However, when abundantly fed and kept at a proper temperature, the hydras that have budded one upon another separate but tardily. Trembley has thus been able to obtain small trees formed of twenty superposed hydras whose digestive cavities all communicated. These hydras, which are apt to separate at the least accident, when they remain united under favorable conditions, constitute but one and the same organism; that is, a zooid. In fact, the majority of the animals allied to the hydras remain in this zooid state permanently (Fig. 3). All the individuals generated

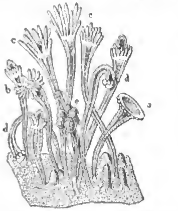

FIG. 3.—Hydractinia echinata. Fragment of a hydrozooid magnified about fifteen times: a, b, c, nutritive merids diversely expanded; d, d, tactile merids; c, reproductive merids.

one upon another constitute arborescent zooids, whose form is often definite. To obtain such a result, it suffices that the hydras shall produce a sheath which extends over the buds when they are formed and protects them against accidents and consequently favors the union of all the individuals. The organisms thus formed may be called hydrozooids, and the merids that constitute them may be styled hydromerids.

Since, in a hydrozooid, the digestive cavities of all the hydromerids communicate with each other, it may happen that a portion of the merids suffices for capturing and elaborating the quantity of food necessary for all. The others will therefore be able to do without a mouth. Their non stimulated digestive faculties will become enfeebled, while their faculties of motion or sensitiveness will become exalted and their form be consequently modified. In fact, in a very large number of hydrozooids (Fig. 3) we distinguish, by their form and very different functions, nutritive merids, prehensile merids, tactile merids, defensive merids, fixing merids, reproductive merids, etc. Social life here, as in human societies, has led to a division of physiological labor, polymorphism and solidarity, since our dissimilar merids can no longer separate from each other without exposing themselves to the danger of dying.

As a general thing, a certain number of merids become modified around reproductive ones in order to form a protecting apparatus for them. One of the most remarkable cases, by reason of its frequency and its consequences, is that in which four prehensile merids form a verticil beneath a reproductive merid, which is provided with a mouth, but the tentacles of which are often abortive. When such prehensile merids are agitated in water by reason of the resistance of the liquid, they draw to themselves simultaneously the region of the internode upon which they are

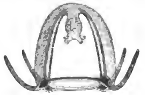

FIG. 4.—Reproductive hydromerid or medusa of Podocoryne carnea, free and completely developed.

fixed and expand it into a bell that hangs down around the reproductive merid. Naturally, this bell carries by its free edge the four prehensile merids. It is contractile, and every time that it closes it drives the amassed water into its concavity. The expulsion of this water brings about a movement of recoil of the bottom of the bell, the peduncle of which, pulled by these abrupt motions, finally breaks. The bouquet of five hydromerids thus set at liberty possesses all that is requisite to allow it to live in an independent manner—a mouth, a stomach, a locomotive apparatus, merids serving as organs of prehension, and reproductive organs even. This bouquet thereafter becomes an autonomous organism. It is what is called a medusa (Fig. 4). A medusa is a hydrozooid. Every association of hydromerids upon which one of these forms, comprising, therefore, merids and zooids, will, in a general

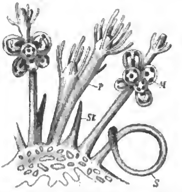

FIG. 5.—Fragment of a hydrodeme of Podocoryne carnea, formed of nutritive hydromerids, P, tactile hydromerids, S, defensive hydromerids, St, and reproductive hydrozooids, or medusæ, M. (Magnified about fifteen times.)

manner, be a deme, and in the species, a hydrodeme (Fig. 5).

Some singular hydrodemes, instead of fixing themselves to the ground, as usually happens, attach themselves to a bubble of air and then constitute floating hydrodemes. In such hydrodemes, a certain number of medusæ cease to serve for reproduction and operate as locomotive organs, which work in concert to assure the displacement of the hydrodeme. The hydrodemes thus formed exhibit, with a definite shape for each species, a very great variety of structure. They constitute an entire class of hydro-medusæ, that of the Siphonophoræ (Fig. 6).

The hydromerids exhibit still another mode of grouping, which ends in the formation of a radiating organism called corallizooid, the type of which is the sea anemone (Fig. 7). These corallizooids are ordinarily grouped into coralliodemes, and constitute a class of polyps also, that of the Coralliens.

FIG. 6.—Siphonophora or floating hydrodeme. (Capalia [illegible].) Pn, float containing a bubble of air; S, locomotive medusæ; P, nutritive merids; D, protective merids; Sk, prehensile merids.

The medusa is the reproductive form of the primitive hydrodemes. It grows upon the hydrozooid like a flower upon a plant. It happens in an entire series of polyps that the hydrozooid assumes less and less importance. The egg appears to hasten toward the production of the medusa, which it ends by directly forming. This haste of the egg toward the formation of a complicated organism, and which is observed, too, in the Siphonophoræ, is a phenomenon found in the entire animal kingdom. It is the phenomenon of embryonic acceleration or tachygenesis. Its importance is such that comparative embryogeny is, at the bottom, only a study of its laws. The medusæ of direct development form the class of Acalephs, whence appears to be derived that of the Ctenophoræ.

The ties that connect the organisms of the series of polyps therefore appear here of extreme simplicity. The limitation of the size of the merids, the germination or budding, the association of the merids due to budding of one upon another, their differentiation, the division of labor among them, and the solidarization of certain merids announce the advent of the merids

FIG. 7.—Sagartia nivea. A corallizooid formed by hydromerids arranged in radii.

and consequently the transformation of the hydrozooid into a hydrodeme, the solidarization of all the parts of the hydrodeme announces the formation of the Siphonophoræ; and finally, embryonic acceleration leads step by step to the direct production of a hydrozooid by the egg. Such are the stages traversed. It would be easy to show entirely analogous ones in the series of Sponges or in that of the Echinoderms.

In these three series, the merid, having made its exit from the egg, which for this reason may be called the oomerid, fixes itself. Let us now suppose an oomerid free, as are all those that are notably heavier than water. In this case, it will not be able to raise itself erect and wait with open mouth for food to be brought to it by the surrounding water, and yet the budding will not disappear on that account, but will take place under very peculiar conditions.

Submitted to the necessity of searching for food, such a merid will be led to move in carrying to the front the extremity of the body in which its mouth is situated. Therefore, every bud that appears elsewhere than at the posterior extremity of the body will be applied against the walls of the latter during locomotion and be led to fasten itself thereto. The merid will therefore bud only at this posterior extremity, and the zooid resulting from such budding will necessarily be an organism formed of segments placed end to end—a segmented organism, such as an insect (Fig. 8), an earthworm or a leech. It is for the animals thus formed that Cuvier created the branch of Articulates. But all recent researches have shown that the segmentation of the body is not a character peculiar to Cuvier's articulated animals. We see, in fact, segmentation gradually becoming effaced, under the influence of parasitism, in the arthropods that pass by sparing transitions to the Nematoids, the type of which is the Ascaris lumbricoides, or intestinal worm so often passed by children. Under the same influence of parasitism, segmentation is gradually effaced, too, in the annelid worms, which thus pass to the flat ones.

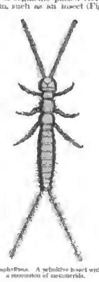

FIG. 8.—Campodea staphylinus. A primitive insect with a body formed of a succession of metamerids.

Despite the apparent unity of their bodies, the mollusks themselves, such as snails and oysters, exhibit in the course of their development very plain traces of segmentation. As for the segmentation of the bodies of the vertebrates, that had already been recognized by Geoffroy Saint Hilaire, merely through a study of the skeleton, the vertebræ and ribs of which are repeated with so much regularity, and it was put out of all manner of doubt by the labors of Balfour, Semper, Sprengel and others upon the structure of the renal apparatus of these animals. So all animals whose body is not ramified by budding, and which get beyond the state of merid, have a segmented body or one derived from animals whose body was segmented. They have been produced by the same mechanism as the ramified animals—by budding, only such budding, instead of being exercised in an irregular manner, as in the fixed merids, has been rendered regular by the exercise of locomotion, the faculty of which has been preserved by the heavy merids.

Embryogeny demonstrates that the merids that are the progenitors of segmented organisms are very likely rotifers (Fig. 9). The lower annelid worms are pro-

duced, in fact, under what is called the "trochosphere form" (Fig. 9), which is represented almost exactly by a rotifer of the Philippines, the Trochosphæra æquatorialis (Fig. 10), and it is also under this form that are produced the majority of the mollusks. So, too, the lower Crustaceans are all produced under what is called the "nauplius form" (Fig. 10), which is also nearly recalled by certain other rotifers—the Pedalions (Fig. 11).

The worms, mollusks and vertebrates probably descended from normal rotifers, and the arthropods and nemathelminthes, according to the recent researches

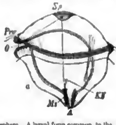

FIG. 9.—Trochosphere. A larval form common to the annelid worms and mollusks. (Highly magnified.) Sp, nervous plate; Prv, band of vibratile cilia used for locomotion; O, mouth; KS, kidneys; Ms, first rudiments of the internal tissues; A, posterior orifice of the digestive tube.

of De Zograf, from rotifers that have become cuirassed with chitine.

Starting from this conception, the entire history of the segmented organisms is of remarkable clearness, and is closely connected with that of the ramified organisms.

Two conditions of existence of the merids, which are themselves connected with the relative weight of such organisms, explain that in the polymerid animals there were two types of structure, and two only, and that one of these closely recalls the type of structure of plants, which, like them, are fixed. The same theory, therefore, embraces the history of the organic complication in the vegetable as well as in the animal kingdom. Such a result, obtained not by a simple effort of the imagination, but by the strictly scientific grouping of indubitable facts, is worthy of our attention, since it gives to the investigation of comparative anatomy and

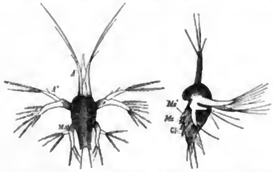

FIG. 10.—Nauplius or larval form common to all the crustacea (back and profile views). embryogeny a precise method. It furnishes an explanation of the partial laws previously expressed, shows their raison d'etre, determines reciprocal relations, and, finally, closely connects biology with sociology, which is merely the terminal stadium thereof.

Nevertheless, an endeavor has been made in recent times to give explanations of the segmentation of the body of symmetrical animals that would put it outside

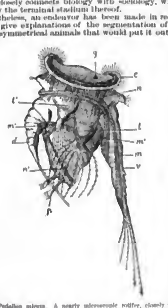

FIG. 11.—Pedalion mirum. A nearly microscopic rotifer, closely resembling a nauplius (side view). g, eyes; c, ciliated ring; m, m', m'', n, n', muscles; dv, odd limbs; t, t', even limbs analogous to those of nauplius; p, tactile organs.

of the general conception that we have just developed. One has wished to see therein the consequence of the undulations of the body of an annelid worm about to swim—undulations that would have broken in a regular manner either the muscular fibers or the genital organs primitively arranged in the interior of the body in two solid columns.

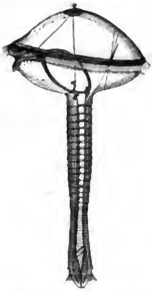

FIG. 12.—Trochosphere of the same species that is shown in Fig. 9, and which has already produced a large portion of the body of an adult annelid worm. The segments are so much the younger and consequently so much the less developed in proportion as the posterior extremity of the body is approached.

An endeavor likewise has been made to explain this remarkable and general division of the body into successive segments by admitting that, in order to increase its digestive power, the intestine has been regularly folded and has subsequently caused the folding of the walls of the body. It has been said, too, that the segmentation is the result of the too great dimensions attained by the organism, which has been obliged to divide into secondary organisms, just as a large country is divided into provinces or departments. It has been connected by some with the formation of the genital segments, which would have primitively detached themselves one after the other, as still do those of the Tænias or tapeworms. In the first hypothesis all the segments

FIG. 13.—An Autolytus that has produced a head toward the middle of its body, and is upon the point of dividing into two.

of the body must have formed simultaneously in the adult animal. On the contrary, they form successively and only in the young, as shown in Fig. 12. The second hypothesis could be applied neither to the arthropods nor to the worms, whose digestive tube remains nearly straight, save in a few very modified forms. Now the segmentation of the vertebrates is manifestly of the same nature as that of the annelid worms, and it is not necessary to invent a particular explanation for it. Before this second hypothesis, moreover, rises the same objection as before the third, to wit, that, according to both, the segmentation must have been specially

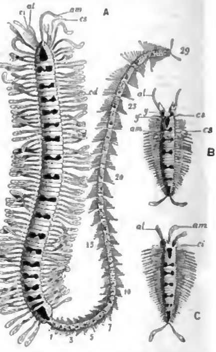

FIG. 14.—A. Myrianis. An annelid worm from which have budded twenty-nine young ones at its posterior extremity. B, Male individual, produced by budding, and that has become free. C. Female individual of the same. am, al, antennæ; ci, cd, cs, tactile cirrhi.

marked in the organisms of larger size, or has especially reached its full effect in the humblest worms, the Syllidians, the Naidians and the Microstomes. As might have been expected in these very simple and very primitive forms, the segments have preserved such an independence that they may be separated from each other by groups, either because there is produced toward the middle of the body a head and a tail that complete two animals designed soon to live each on its own account, as is seen in the Autolytus (Fig. 13), or because the animal, after reaching a certain size, gives rise in buds at the posterior extremity of its body, as do the Myrianes (Fig. 14), to a chain of small ones that detach themselves one by one in commencing with that which is situated the farthest behind. As a general thing, the zooids that detach themselves thus are sexual, while the one from which they isolate themselves is asexual. They are even capable of exhibiting characters quite different from those of their parent. They are, consequently, reproductive zooids comparable to the medusæ, from which they differ especially in the arrangement of the parts, which are verticilliate in the medusæ and placed

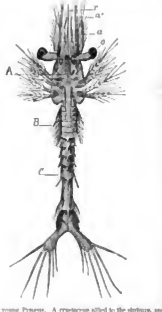

FIG. 15.—Very young Peneus. A crustacean allied to the shrimps, and in which the thoracic region, B, and the abdominal region, C, are in the process of formation back of the head. r, beak; a, a', antennæ; o, eyes.

end to end in the annelid worms. Finally, the fourth hypothesis differs from our general theory only by the very useless introduction of the function of reproduction into the appearance of budding.

The explanation of the metameridation that results from what is calle the theory of animal colonies presents none of these difficulties. Moreover, if it is the

simplest worms that are the most distinctly segmented. If, when the segmentation is merely temporary, it is always in embryos that it shows itself, and if in every series of the animal kingdom it is always the lower forms that are produced in the state of merids, that implies that the metameridiation is the very mechanism of the formation of the body, and not a method of improvement of a body already formed.

A segmented animal is therefore a linear colony of merids, as Durand de Gros perceived as long ago as 1851 and Dugas as long ago as 1832. In such a colony the same phenomena are exhibited only in a hydrodeme. Polymorphism and the division of physiological labor lead in the first place to the formation of a sensitive and buccal region—the head. We have often seen the appearance of a reproductive region which is capable of isolating itself, as in the medusæ, and exhibits characters that are quite peculiar. In most cases, however, things do not go so far as this. Back of the head there forms simply a locomotive region or thorax, a visceral region or abdomen (Fig. 15), and more rarely an attenuated region or tail. These regions often possess a certain physiological autonomy. From this point of view they may be considered as zooids, and consequently the upper metamerid organisms have the rank of demes.

The linear arrangement singularly facilitates in such demes the grouping of the similar parts of the merids in these sorts of syndicates or corporations, which are the tissues, the organs and the apparatus. The material relations are established by a circulatory system, and the relations of co-ordination by a nervous system, an undivided property among all the merids, and the unity of which completely assures the solidarity of all the parts. In the highest vertebrates there is even produced an extreme centralization, which they pay for by a fragility that is relatively greater than that of the lower vertebrates.

This centralization in the vertebrates does not prevent the constituent merids of the body from remaining clearly distinct, as is shown by the entire organization of the lower vertebrates and the method of development of the higher ones. There are, on the contrary, cases in which certain conditions of existence (parasitism, fixation to the ground, habitation in the interior of a shell or hole, etc.) may lead to the fusion of all the merids into a single undivided body. The Gephyrians, the flat worms, the Arachnids and the parasite Crustacea show us all the phases of such fusion, which is almost entirely realized in the Nematoids and Mollusks.

On another hand, owing to tachygenesis, favored by the accumulation of a larger or smaller quantity of nutritive material in the egg, the precocious birth and the slow development, merid by merid, of the lower forms are replaced by so rapid a development that all the pieces of the organism seem to form almost instantaneously, and that the latter leaves the egg with its definite form, having nothing further to do but to grow.

Here, then, we are in possession of a mechanism owing to which all the successive stages of the organic complication may be easily chained one to the other. Were the first organisms simple plastids, as are now all individuals at the beginning? There is no reason why the same mechanism should not have been applied to the gradual formation of organisms in the course of time gone by, and be applied to the present formation of individuals. There exist, then, necessary ties between paleontology and the comparative morphology of the present forms and their embryogeny.

If there still exists any doubt as to the first causes of budding, there is no doubt about the fact itself, and it suffices to establish the proposition that the victory of organisms in the struggle for existence has been obtained by association. The associations have been gradually fortified by reciprocal sacrifices that have been made by individuals, without, however, ever abandoning their personality, save in a few degraded types. Discipline, the constitution of common organs and that of social reserves, accompanied always with personal reserves often transmitted hereditarily, have been the most active factors of improvement. Upon the whole, it is therefore the practice of what we call social virtues that has made organisms powerful and assures their duration. It would be easy to establish the fact that, when once the form of the body was realized, force began constantly to succumb to intelligence. It was by the great development of their nervous system that the vertebrates first characterized themselves, and in this respect they did not cease to progress until human reason finally dominated the organic world. The doctrine of evolution, then, does not, as might be thought by superficial readers of Darwin, afford any support to those who believe in the exclusive triumph of material power, and who have got into the habit of glorifying self, in excusing themselves on the plea of the necessities of the struggle for existence. The history of the living world, on the contrary, shows us intelligence everywhere triumphant, and association (that is to say, the constant sacrifice of a portion of one's personality) as the essential condition of progress, even in material well-being. This history teaches us solidarity before all things, and no lesson could be more consoling at an epoch in which so many minds have closed themselves to other light.—Edmond Perrier, in La Revue Larousse.

VITALITY OF SEEDS.

"M. C. De Candolle," says Cosmos, "in presenting some considerations to the British Association relating to his experiments on the vitality of seeds, cited several curious facts that it may be interesting to mention. Thus he related the fact observed in Greece, where, after removing the refuse of a silver mine that had been long unworked, the workmen saw a whole flora appear, evidently from seeds that had been buried under the debris and that must have been so buried not less than 1,500 years. One of M. De Candolle's hearers, an Irish farmer, then mentioned an analogous fact: he had noticed that certain fields that had been uncultivated from time immemorial became covered, as soon as they were tilled, with the wild poppy. It would be interesting to know whether the poppy had not been growing near by; the fact would not be comparable with that related by M. De Candolle unless no poppies were to be found in the vicinity. Another auditor, Mr. Seward, a distinguished paleobotanist, says the Literary Digest, remarked that facts of the same kind may have taken place long ago; he thought, in fact, that seeds covered by the glaciers of the ice age may have preserved their vitality and may have germinated centuries later after the retreat of the glaciers."

TREVORIA CHLORIS.

This is the second of a number of new genera of orchids which I have discovered during the twenty-one years of my travels in the Andes. Both Trevoria and my Gorgoglossum are old acquaintances of mine, but owing to their great rarity, and their growth in habitats very difficult to reach, insufficient floral material have made it hitherto impossible to publish them.

Gorgoglossum Reichenbachianum, Lehmann (MS., 1879), was met with in December, 1879, in one single specimen on the Western Andes of Ecuador, at an elevation of 300 to 600 meters above sea level. The single specimen was duly given to the late Professor Reichenbach; but the flowers having lost their pollinia, he did not venture to describe the plant, and it wandered with some 3,000 other numbers of the herbaria for twenty-five years to the grave at Vienna. Some eleven years later, when I knew already the fate of my unique Gorgoglossum, I undertook an especial journey to the locality in order to secure a few plants for cultivation in one of my estates in the Cauca. Only five plants were found, of which to-day one exists in my possession and another in that of Sir Trevor Lawrence, the rest having been lost on the sea voyage.

My first acquaintance with Trevoria occurred in 1887. Only three specimens were seen, bearing thin, drooping spikes, about 40 cm. long, of thickly-set seed vessels, but no flowers. The plants I tried to take to the Cauca for cultivation, but, alas! they were stolen from me by some rascal at Esmeraldas during my absence from the steamer, together with a number of other botanical treasures. Nothing more was seen or heard of this plant, which, by the by, looked quite novel and interesting until last year, when during an exploration of a certain portion of the Western Andes of Colombia, with a view of projecting a map on behalf of the Cauca government, a few plants of this species of orchid were observed. The species found in Colombia is, however, quite distinct from that of Ecuador. The latter grows at an elevation of 500 meters above the sea, and produces flower spikes of from twenty to thirty flowers, the size and character being as yet unknown, while the Colombian one inhabits a region from 1,500 to 1,700 meters above the sea (as far as observed), and bears racemes of only three to five, commonly only three flowers.

As a genus, Trevoria is very characteristic and distinct. Its nearest neighbors are Coryanthes, Schlimia, Stanhopea, and Gorgoglossum, but it is distinguishable at first sight from either of them. Trevoria chloris produces large fleshy wholly green flowers, placed on the drooping spike in the manner of the buckets on a dredger chain. The narrow disk of the lip and the thick coriaceous process at its base are the only different colored organs in the flower; they are pure white. Both from a morphological and also from a physiological point of view this genus is very novel and interesting. The position of the column and lip, standing straight upright in an urceolate manner, the thick fleshy process at the base of the lip being of exactly the same length as the column, and standing parallel and closely adpressed to that organ, the peculiar shape and insertion of the stigma and several other items are wholly novel, and the arrangement of them to each other may set at naught some of the pet views of modern hypercritical speculators with respect to the aid of insects in the fertilization of orchids, or give rise to quite new conceptions.

I have named this genus of Orchidaceæ in honor and commemoration of Sir Trevor Lawrence, one of the most enthusiastic orchidists that ever lived. Trevoria has to answer our purpose; Lawrencia and Lawrenceella being already in existence in Compositæ and Malvaceæ respectively. May Sir Trevor's love of orchids perdure sempervirent as Chloris the goddess of flowers. Popayan, February, 1897. F. C. Lehmann.—The Gardeners' Chronicle.

AMERICAN TEA CULTURE.

Secretary of Agriculture Wilson has received a report from a veteran horticulturist whom he sent recently to investigate the tea farming industry carried on at Summerville, S. C., with a view to ascertaining the prospects of profitable growth of the tea plant in this country, should it be decided to introduce it here as an industry.

The report says the labor question is the most important one in the economics of this business in this country. It estimates the minimum cost about eight times as much to pick one pound of tea in South Carolina as that paid for the same service in Asia. The report suggests that it seems impracticable to compete with the cheap Oriental labor, and while some of the processes of development have been delegated to machinery, the picking of the leaves, requiring discrimination in selection, has to be done by hand. The problem has been ingeniously met in this Southern field by establishing a small colored school where tea picking is included in the curriculum, and the young scholars, after some instruction, prove good pickers.

As to the future of tea culture in the United States and the encouragement for its extension, the report

quotes the promoter of the South Carolina tea fields as saying that if he were twenty years younger, he would plant 500 acres as rapidly as he could procure the plants, thus indicating his faith in tea raising as a profitable industry. The report urges the development of knowledge as to tea raising by means of schools of instruction.

LIFE ON THE PLANETS.

By M. J. Janssen.*

(Having shown how all astronomical discovery, concluding with spectrum analysis, points to a similarity of constitution in the earth and the heavenly bodies, M. Janssen continues:)

All this whole forms a single family, the members of which have a common genesis and have been formed with the destiny of becoming worlds like ours. Their movements around the central star which enchains them by its powerful attraction are subject to the same laws, and that star, by virtue of its high temperature and the immense reserves of force it contains, sheds upon them those influences and radiations which go to place upon their surface the generative elements of life. Yet while these stars present so strict analogies in formation and nature, they do not by any means indicate the same degree of advancement in what may be called geological or rather planetary evolution, or that which tends to the appearance and development of life on their surface. Here the conditions of mass, of distance from the sun, and doubtless other circumstances still unknown, come in to order the epoch and extent of these developments; but we can affirm, without going beyond the inductions permitted by the condition of science, that if life has not yet been established directly on the surface of any of the planets, we have very strong reasons for assuming its existence on some of them. We may regard this conclusion as gained from the long labors of antiquity and modern discoveries.

We say that, while the problem has not been directly resolved by the eyes, it has been worked out by an aggregate of facts, analogies, and rigorous deductions that leave no room for doubt. This is the mature and perfect fruit of science. It is the view of intelligence, as certain an authority and of even a higher and nobler order than the senses. I say further that what we know of the unity of the chemical composition of the matter of the sun, the stars, and the nebulæ permits us to make new inductions respecting the part performed by the bodies which are on the earth the most important factors of the phenomena of life. It is thus infinitely probable that hydrogen, oxygen, nitrogen, carbon, and especially water, which on the earth are the indispensable constituents of vegetable and animal life, fill a like office not only in the planets of our system, but throughout the universe.

Water in particular, by virtue of its chemical functions and the properties with which it is endowed in the solid, liquid, and gaseous states—properties which are so admirably fit for the accomplishment of physiological processes—is a unique substance, and the search through the whole series of chemical compounds for any body that can take its place has been in vain. The discovery of the spectrum of the vapor of water permits us to deduce and assert its presence in the atmospheres of the planets and in those of a whole class of stars as well. Drawing from these results the fact of the presence of hydrogen, one of the generative gases of water, in nearly all the stars, we are justified in supposing an extreme diffusion of that important element from the point of the unity of the phenomena which control the production and maintenance of life.

Thus, the more science advances, the more is that great law confirmed and established of unity in the material elements, in the compounds formed of those elements, and in the constitution of the stars and the parts they perform in the grand whole.

Are we authorized now to assume from this a unity of forms that life may put on not only in the sister planets to ours, but also in the other systems of worlds scattered through the skies? May we especially push our inductions still farther and higher, conclude from such material unity upon a mental and moral unity, and say that, as there is only one physics and one chemistry in the universe, there are also only one logic, one geometry, and one moral, and that the beautiful, the good, and the true are identical aim of the universal order everywhere?

Science, embracing in its results only immediate and demonstrated facts, does not warrant us going so far as this, but with the truths it unfolds to us seems to invite us toward it.

There were brilliant minds in antiquity, which, upon bases otherwise restricted, conceived and proclaimed verities concerning the world and the universe which the most modern science has only been able to confirm.

Let us, then, respect these cheerful speculations. If they are still only of things preconceived, who can affirm that science will not make them real to us tomorrow? By establishing the laws and harmonies of the material world, astronomy prepares us for the conquest of truths of a still higher order.

We can say then plainly that the subjection of natural forces and the reign of man over Nature are only the first fruits of science. It prepares other fruits for its votary of a higher and more precious order. By the beauty of the studies to which it invites him, by the grandeur of the horizons which it opens to him, and the sublimity of the spectacle it gives him of the laws and harmonies of the universe, it promises to win him away from his present preoccupations, which are perhaps too exclusively positive, and will restore to him under a new form and in an incomparable grandeur that taste for elevated poetry, that enthusiasm for the beautiful, and that reverence for the ideal which are among the most imperious needs of the human soul and which it never abandons without peril.

The English war office authorities are a good deal troubled over the results of using cordite for artillery. At a recent practice at Okehampton, out of eighteen guns of the Horse Artillery using cordite in place of ordinary powder, seven guns became useless after firing only two rounds each.

* From his remarks at the annual meeting of the French Academy of Sciences, October 21, 1896.—Translation from the Revue Scientifique by Popular Science Monthly.

THE

Scientific American Supplement.

PUBLISHED WEEKLY.

Terms of Subscription, $5 a Year.

Sent by mail, postage prepaid, to subscribers in any part of the United States or Canada. Six dollars a year, sent, prepaid, to any foreign country.

All the back numbers of The Supplement, from the commencement, January 1, 1876, can be had. Price, 10 cents each.

All the back volumes of The Supplement can likewise be supplied. Two volumes are issued yearly. Price of each volume, $2.50 stitched in paper, or $3.50 bound in stiff covers.

Combined Rates.—One copy of Scientific American and one copy of Scientific American Supplement, one year, postpaid, $7.00.

A liberal discount to booksellers, news agents, and canvassers.

TWENTY-FIVE TON PORTABLE CRANE AT SOUTH SHIELDS

TWENTY-FIVE TON PORTABLE SELF-PROPELLING STEAM CRANES AT SOUTH SHIELDS.

WE illustrate herewith one of two cranes which have just been erected and tested on the new wharf belonging to the Harton Coal Company (Limited), at South Shields. The wharf, which is of wood, has a frontage of about 600 ft. to the river, and has been constructed to the designs of Messrs. Sandeman and Moncrieff, C.E., of Newcastle-on-Tyne, who also prepared the general specifications for the cranes. In these it was provided that the load should be lifted at 60 ft. per minute, and that the crane should be capable of making a complete revolution in 30 seconds. A calculated factor of safety equal to 8 was specified for all parts, while under maximum load the pressure between the wheels and the rails was not to exceed 10 tons. It was further provided that the center of gravity should not deviate more than 3 ft. 3 in. from either side of the center of revolution with the load on or off. The general appearance of the crane is well shown in our illustration. The track on which the crane travels consists of a double rail at each side, with a space between of 2¾ in., the carriage wheels having central flanges. The gage is 21 ft. from center to center of the groove thus formed.

The wheel base is 38 ft. 6 in., there being 12 wheels on each side. These wheels are 2 ft. 6 in. in diameter, and are spaced at 3 ft. 6 in. center to center. The whole of these 24 wheels are fitted with Bessemer steel tires.

Each corner of the carriage is supported on six wheels. The maximum radius of the jib is 35 ft. and the minimum radius 25 ft. The radius is very quickly varied between these extremes, by the arrangement described below. The tie rods suspending the jib are attached to the piston rod of a hydraulic cylinder, which is of Siemens cast steel, lined with copper. There are a pair of double acting pumps with gun metal lined barrels, operated direct from the piston rods of the hoisting engines; these pumps can be readily disconnected when it is not required to vary the jib radius. They draw water from a supply tank and discharge back into the same tank, or at option into the upper end of the hydraulic cylinder. When it is desired to lessen the radius of the jib, the discharge to the tank is closed, and the water acts on the piston and lessens the radius at the rate of 1 ft. per second. The radius is increased by allowing the water to escape to the tank.

The main engines for hoisting have a pair of 16 in. cylinders, and are always in gear with the hoisting barrel, by duplicate steel wheels and pinions, single purchase. The link reversing motion is operated by a steam cylinder very quickly, and with little exertion to the driver. There are also a pair of separate engines for slewing, and a third pair of engines for propelling the crane, this being effected by the vertical shaft and bevel gearing shown in the woodcut. These engines also drive a capstan attached to one corner of the carriage for manipulating the coal wagons on the wharf, and putting them on and off the cradle by which they are lifted and discharged into the vessels.

The body of the carriage is high enough to allow two trains of loaded wagons to pass underneath. The boiler is 21 ft. high and 6 ft. in diameter, and is certified by Lloyd's for 75 lb. working pressure. The total weight of each crane in working order is about 130 tons. The official tests were highly satisfactory in every way, the prescribed conditions being all fulfilled.

The cranes were designed and built by Messrs. George Russell & Company, of Motherwell, near Glasgow.—Engineering.

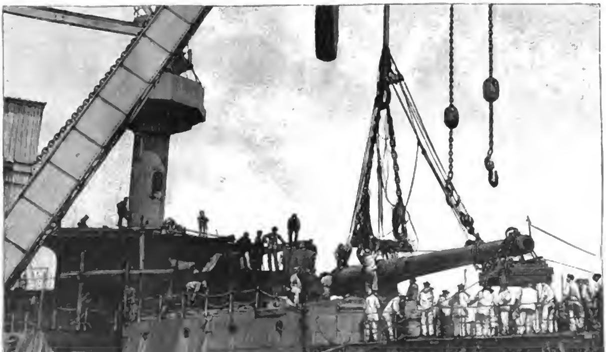
THE DERRICK AND THE TWELVE INCH GUN.

THE BOUVET AND HER NINETY-NINE THOUSAND POUND GUN.

THE French armorclad Bouvet, which, at the beginning of June, entered upon the most active phase of her armament, is one of the most recent and powerful battleships now afloat.

Her high and slightly incurved stem, armed with a formidable ram, her somewhat low, pointed stern, and her rounded sides that bulge at the load water line, represent her well seated upon the water and will certainly contribute toward assuring her stability, even upon the roughest sea.

The [illegible] of the water lines necessary for the speed of 17.5 knots that the vessel must make, and the very compressed form given her topsides at the median part, so as not to interfere with the field of firing of the guns of the side turrets, but to allow them [illegible]



PUTTING THE TWELVE INCH GUN IN PLACE ON BOARD THE BOUVET

to have their maximum effect in direct fire aft and ahead, give this mass of steel of more than 12,000 tons displacement an elegant appearance.

It is especially during this period of armament, while the vessel, still light, is sitting high above the water and thus showing her entire belt of armor, that it is possible to obtain an idea of her great defensive power. This is carried to the extreme on the Bouvet, where the protective belt of more than six feet in height and 16 inches in thickness extends from stem to stern, thus strengthening the ram with its entire mass, but at the stern assuming a very hollow tapering form to prevent the eventual shock in the axis and protect the rudder and three screws.

An armored deck $2\frac{3}{4}$ inches in thickness rests in the form of a turtle's back upon the upper edge of the belt of armor, in order to assure the protection of the most valuable and delicate belongings of the vessel. To prevent the great damage that might be caused by rapid fire light artillery, and by shells filled with powerful explosives, in the immediate vicinity of the load water line, the ship has been covered with a second cuirass, above the principal belt, but only $3\frac{1}{2}$ inches in thickness, and with an armored deck especially designed to prevent the entrance of water and allow the vessel to preserve its equilibrium in case of grave damage being done it.

The offensive power of the Bouvet resides less in the number of her guns than in the extreme care taken to protect them against the fire of the enemy.

The $10\frac{3}{4}$ and 12 inch pieces, which form the most important part of the armament, are each inclosed in a movable turret protected with 14 inch plate and completely closed, and having no other aperture than the one strictly necessary for the muzzle of the piece and for upward pointing.

Our ancestors would be much astonished to see with what ease and rapidity the powerful steam derrick of the port of Lorient, capable of lifting a weight of 150 tons, proceeds to the putting in place of the heavy pieces that enter into the armament of an armorclad. It is child's play for the derrick to seize, upon the wharf, the huge 12 inch gun, weighing 99,000 pounds, and balanced at the muzzle with one or two tons of pig iron, and then, turning upon its rollers, to place the breech opposite the narrow aperture in the turret. Here the final operation becomes original, in the sense that, in order to cause the gun to enter the turret, gangs of men, working at the capstan, are obliged to cause the 12,000 ton vessel itself to move forward until the breech, on entering the fork, hangs over its carriage.

The artillery of the Bouvet will consist of two 12 inch and two $10\frac{3}{4}$ inch guns, eight $5\frac{1}{2}$ inch rapid fire guns, and thirty small pieces distributed here and there upon the bridges and the military mast. It will have two torpedo tubes, and carry a crew of 31 officers and 600 men.—L'Illustration.

USE OF COMPRESSED AIR IN RAILROAD SHOPS.

THE Illinois Central Railroad at their Burnside shops use compressed air for the following purposes:

Elevating sand at engine sand house, elevating oil at oil house, hoisting heavy castings and parts of machine tools, etc., forcing couplings on air hose, operating cylinder boring bar, operating valve facing machine, filling cylinders of hydraulic presses, removing and applying driving tires, testing water pumps after repairs, drilling with motor, tapping with motor, reaming with motor, cleaning boilers, cleaning machinery, punching jacket rivet holes, taking old paint off tin roofs, rolling and beading flues, chipping, cutting, calking, small bull dozer, elevating water from deep wells, testing air and driving brakes, elevators in storehouses, operating letter presses, cutting out staybolt stubs, jacking up cars and trucks, cleaning interior of coaches, cleaning upholstered work, burning paint off coaches, painting cars, sandblast ends of cars, gasoline heater, cutting off staybolts, screwing in staybolts, rivet forges, one blacksmith forge, pressing in driving box brasses, operating flange clamp, swedging flues. They consider it the best means of transmitting power in and about shops.

THE GREATEST STEAMER IN THE WORLD.

THE fourth of May of this year saw the launching of the largest steamer of all merchant navies of the world. The twin screw steamer Kaiser Wilhelm der Grosse was built for the North German Lloyd on the dry docks of the Vulcan, at Bredow, near Stettin. Her length on the water line is 190·5 meters, length over all 198 meters. She is 20·1 meters broad; the height from keel to deck, 13·1 meters. The hold represents a volume of 12,800 tons; the total displacement of the ship is 20,000 tons. The boat is built of steel, according to the rules of the German Lloyd, and under the supervision of the inspectors of the German and North German Lloyds, and ranks among the highest class boats.

All possible measures have been taken for the safety of passengers, cargo, and the boat itself, in accordance with the most modern improvements. The ship's hull contains fifteen watertight bulkheads and one machine bulkhead, on either side of which the engines are located. They are independent of one another. By the bulkheads the Kaiser Wilhelm der Grosse is divided into eighteen separate watertight compartments. Throughout her whole length she is provided with a double bottom.

There are two triple expansion engines, with four cranks and four steam cylinders, which lie one behind the other. Besides the two chief engines there are no less than sixty-eight supplementary engines (for electric light, pumping machinery, etc.), with altogether 124 steam cylinders.

To avoid the rocking and the concussion due to the immense engines, these have been balanced in their parts by the well known Schlick system. The two engines will have a horse power of 30,000. They are fed from fourteen boilers, and burn 450 to 500 tons of coal daily. The speed of the boat will be twenty-two knots. There is accommodation for 400 first cabin, for 340 second cabin, and 800 steerage passengers.

The specially large and elegant saloons, throughout of German workmanship and German materials, are masterpieces of German production. The first saloon is built in Italian early Renaissance style; in the recesses are represented the residences of the emperors from ancient up to modern times.

On either side of the first saloon are attached small drawing rooms. The other rooms are finished partly in Rococo style, partly also in Italian Renaissance and Queen Anne style. There are provided a reading room, a music room, smoking room, etc. All rooms are distinguished by the most artistic furniture of excellent taste and comfort. The cabins hold two or three persons each. Besides there are a few state rooms furnished for special occasions. Essential improvements too are made in the accommodation of the steerage passengers, both in their position and in the space and comforts allowed.

The crew consists of no less than 450 men, of which number 208 are employed in the engine room. The ship carries twenty-four steel boats. Another notable feature are the extensive precautions taken against fire, also the huge pumping plant of the steamer. The boat has two masts, and four immense funnels, which give it a most imposing appearance.

Our cut represents the gigantic steamer standing on end beside the spires of the Cologne Cathedral. It gives perhaps a better idea of the immense length than any other means could convey. We are indebted for the illustration to Illustrirte Zeitung.

THE KAISER WILHELM DER GROSSE AND COLOGNE CATHEDRAL.

A PRESIDENTIAL CAR.

THE Railroad Car Journal has originated a project to build a private car for the President of the United States, from material and appliances contributed for the purpose by the car building and affiliated industries.

It is proposed to construct a private car excelling anything of this kind which has been done before in the substantial character of its construction and in the completeness and convenience of its furnishings and decorations.

The projected car will be a complete exposition of the art of car building, demonstrating to the world the surpassing excellence of this industry in the United States; and it is to be presented to the nation, as a tribute from the car building fraternity, for the personal and official use of the successive presidents.

The designs and specifications for the car are being prepared by the Railroad Car Journal, under the supervision of a committee of twenty-five prominent and representative master car builders and superintendents of motive power of various railroads, thus insuring the end that the proposed car shall represent the skill, ingenuity and experience of the American car builder.

Much of the necessary material required for its construction has been tendered by leading dealers and manufacturers in the railroad supply trade, and the projected movement offers an exceptional opportunity to firms engaged in business which, while not directly associated with the car building industry, make and supply various articles and materials which will be desired for the furnishing and decoration of so elaborate a vehicle as a private car for the use of the President of the United States.

Offers of contributions of material, furnishings, appliances or utensils should be forwarded to the Railroad Car Journal, New York, for submission to the advisory committee.

A RAILWAY HOSPITAL CAR.

CONSUL MORRIS writes from Ghent: The latest novelty in Belgian railroad matters is the hospital car. It serves a double purpose. In the event of a serious railroad accident, the car may be run to the spot, where the wounded may be picked up and carried to the nearest large city for treatment, instead of being left to pass long hours in some wayside station while awaiting surgical attendance. It also enables the railway companies, at certain seasons or upon special occasions, to transport large numbers of invalids to health resorts or places of pilgrimage. This new hospital car entered into regular service April 27, 1897. The interior is divided into a main compartment, a corridor on one side, and two small rooms at the end. The largest compartment is the hospital proper; it contains twenty-four isolated beds on steel tubes hung upon powerful springs. Each patient lies in front of two little windows, which may be closed or opened at will. Each bed is provided with a little movable table and a cord serves to hold all the various small objects which the patient may need.

The corridor on the outside of the hospital chamber leads to the linen closet and the doctor's apartment. In the latter is a large cupboard. The upper portion is used for the drugs; the lower part is divided into two smaller compartments—one serving as a case for

surgical instruments, the other as a receptacle for the doctor's folding bed. The hospital compartment is carpeted with linoleum or other material to deaden the sound of walking. Various trapdoors in the floor, when opened, disclose to view an ice chest, a compartment for the disinfection of soiled linen, and a provision cellar. If necessary, a portion of the hospital chamber may be transformed into an operating room for urgent cases. Finally, as is customary in this country, a small chapel for religious worship is provided. This car will be put in charge of a surgeon, doctor and nurse, and will be chiefly used to carry invalids from Belgium direct to the miraculous cure of Lourdes, in France. The feasibility of the introduction of such a hospital car on American railroads seems to me beyond question; if run, for instance, during the winter season between any one of several Northern cities and certain well known Southern resorts, it would, without doubt, be well patronized.

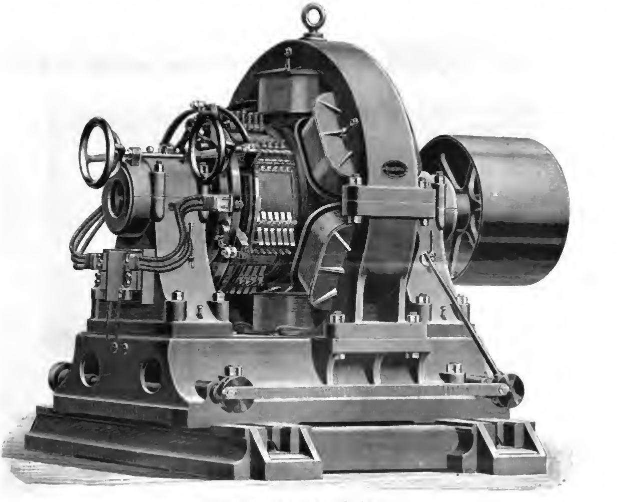
SIX-POLE SEVEN-KILOWATT DYNAMO.

WE illustrate herewith a six-pole dynamo, constructed by the Electrotechnische Industrie (formerly Willem Smit & Co.), of Slikkerveer, Holland. The dynamo in question has been designed to give a current of 600 amperes at 120 volts when running at 450 revolutions per minute. The general arrangement is very clearly shown in the woodcut. As will be seen, the dynamo is belt-driven, and mounted on a cast iron bed, along which it can be traversed by screws when it becomes necessary to tighten the belts. These screws are coupled together, so that a uniform traverse is automatically secured. The armature shaft runs in bearings of ample proportions, while efficient lubrication is secured by a loose ring mounted on the shaft and dipping into an oil bath, the level of the lubricant in which is shown by gage glasses. The field magnets are formed out of steel castings, the pole pieces being cut out of a separate complete steel ring, and bolted into place. The magnetizing coils are wound on iron spools having end flanges of bronze.

The bearing surfaces are of white metal. The armature is of the Gramme type, and is mounted on a six-armed spider of bronze. These arms are sufficiently long to carry the commutator, which thus makes one piece with the armature proper. The body of the latter is built up of extra soft steel stampings half a millimeter thick, paper being used as the insulator. These plates are stamped in two operations, the first of which produces the central hole and the notches for the spider arms, while the second produces the grooves in which the windings are laid. The whole set of stampings are kept together, not by bolts as usual, but by riveting the horns of a bronze end flange to the corresponding arms of the spider, this work being executed while the disks are heavily pressed together. The winding is laid in 200 narrow slots, in each of which are laid six wires, 3 millimeters in diameter, connected up in multiple arc, and carefully insulated.

The commutator bars are of hard drawn copper, insulated with mica, and the diameter of the commutator is, it will be seen, nearly equal to that of the armature itself. Connections of tinned copper are used between these bars and the armature windings. The number of commutator bars is equal to that of the windings, so that the current delivered is extremely steady. These bars are held in place by a clamping ring, and the depth allowed for wear above these rings is about $1\frac{1}{8}$ in. Mica is used exclusively for the insulation of this important part of the machine.

The armature is not keyed on the shaft, but is secured entirely by friction, two iron rings being shrunk over the ends of the spider tube. End motion of the armature when running is limited by a screwed ring shown at the pulley end of the shaft. There are six sets of six brushes each, and the bearing pressure of each separate brush can be adjusted independently of the rest. At the same time by means of one small handwheel all the brushes can be simultaneously raised from or lowered into contact with the commutator, while a second handwheel provides a means of shifting them round through a small arc, so as to find the non-sparking position. Flexible connections are, it will be seen, used between the brushes and the terminals of the machine. The current required for the field magnets is 12 amperes, or 2 per cent. of the total output of the machine.



SIX-POLE SEVEN-KILOWATT DYNAMO.

POWER REQUIRED FOR ELECTRICALLY OPERATED WOODWORKING MACHINERY.

THE following is an interesting report of some electrical tests upon the power required for running woodworking machinery, made by Prof. O. G. Dodge, U. S. N., the work having been done at the navy yard at Washington, D. C. It should be borne in mind that a watt is a volt ampere, and equal to $\frac{1}{746}$ of a horse power. An electrical horse power is equal to the product of the current in amperes and the difference of potential in volts divided by 746. One horse power equals 746 watts, which is the equivalent of 33,000 foot pounds per minute. The results are reproduced from the Electrical Engineer.

In the case of the following tests the mechanical horse power delivered by the motor was determined by tests made under the same conditions as the previous power tests. This was necessary, as in many cases long leads were run to the motor, and the drop was large. In other cases it was necessary to use a rheostat in series with the armature to obtain the required speed. Under these conditions the efficiency of the motor was a variable factor, and a separate test was made in each case to determine the output of the motor. The column of mechanical output is therefore the proper one to use in determining the motor required, and the electrical horse power to be delivered by the generator. The work done is the heaviest required of these particular machines:

Circular rip saw, 28 in. diameter; speed, 1,200 revolutions per minute, or 8,800 lineal feet per minute; arbor pulley, $5\frac{1}{4}$ in. diameter by $8\frac{1}{4}$ in. face; hand feed; motor belted to saw shaft. Motor and saw, idle, 3·4 E. H. P.; ripping seasoned heart oak, $7\frac{5}{8}$ in. thick; feed, 10 ft. per minute, 19·3 E. H. P.

Circular rip saw, 34 in. diameter; speed, 1,500 revolutions per minute, or 9,429 lineal feet per minute; hand feed; motor belted direct to 7 in. pulley on saw shaft. Motor driving saw, idle, 3·2 E. H. P.; ripping seasoned heart oak, 6 in. thick, 10 ft. per minute, 12·8 H. P.; ripping seasoned white pine, $6\frac{1}{4}$ in. thick, 15 ft. per minute, 9·4 E. H. P.; ripping seasoned yellow pine, 2 in. thick, 45 ft. per minute, 10·7 E. H. P.

Circular rip saw, 14 in. diameter; speed, 2,200 revolutions per minute, or 8,067 lineal feet per minute; arbor pulley, 8 in. diameter, 5 in. face; hand feed; motor belted to saw shaft. Motor, idle, 0·96 E. H. P.; motor and saw, idle, 2·7 E. H. P.; ripping seasoned heart oak, $8\frac{1}{4}$ in. thick, 12 ft. per minute, 6·3 E. H. P.

Circular rip saw, 12 in. diameter; speed, 2,200 revolutions per minute, or 6,914 lineal feet per minute; hand feed; belt pulley, $3\frac{1}{2}$ in. diameter, and 8 in. face; motor belted direct to $3\frac{1}{2}$ in. pulley on saw shaft; saw set to wabble for cutting grooves. Motor, idle, 0·96 E. H. P.; driving saw, idle, 2·2 E. H. P.; cutting groove in seasoned walnut, $\frac{5}{8}$ in. by $\frac{7}{8}$ in., 12 ft. per minute, 3·6 E. H. P.

Band saw pulleys, 72 in. diameter; speed, 160 revolutions per minute, or 3,017 lineal feet per minute; belt pulley, 30 in. diameter, 8 in. face; power feed; motor belted to saw shaft. Motor and saw, idle, 12·1 E. H. P.; ripping seasoned ash, $10\frac{3}{4}$ in. thick, feed 6 ft. per minute, 16·1 E. H. P.; ripping seasoned white pine, $16\frac{3}{4}$ in. thick, feed 10 ft. per minute, 16·1 E. H. P.; ripping yellow pine, 12 in. thick, 20 ft. per minute, 18·8 E. H. P.

Band saw pulleys, 42 in. diameter, speed, 350 revolutions per minute, or 3,850 lineal feet per minute; belt pulley, 16 in. diameter, 5 in. face; hand feed; motor belted to saw shaft. Motor, idle, 0·96 E. H. P.; motor and saw, idle, 2·9 E. H. P.; ripping seasoned oak, 12 in. thick, feed 3 ft. per minute, 5·7 E. H. P.; cross cutting seasoned oak, 8 in. thick, feed 5 ft. per minute, 5·7 E. H. P.; ripping live oak, 10 in. thick, feed 3·2 ft. per minute, 5·7 E. H. P.

Band saw pulleys, 28 in. diameter; speed, 480 revolutions per minute, or 3,520 lineal feet per minute; belt pulley, 12 in. diameter, $3\frac{1}{4}$ in. face; hand feed; motor belted to saw shaft. Motor, idle, 0·96 E. H. P.; motor and saw, idle, 1·7 E. H. P.; ripping seasoned oak, 3 in. thick, feed $2\frac{1}{2}$ ft. per minute, 2·3 E. H. P.; ripping seasoned pine, 3 in. thick, feed 4 ft. per minute, 2·8 E. H. P.; cross cut seasoned oak, $3\frac{1}{4}$ in. thick, feed 4 ft. per minute, 2·3 E. H. P.

Daniel's planer, machine bed, 2 ft. 5 in. by 21 ft. 6 in.;

belt pulley, 13 in. diameter by $5\frac{1}{4}$ in. face; speed, 850 revolutions per minute; speed of cutting edges of tool, 10,400 ft. per minute; power feed, 12 ft. per minute; motor belted to countershaft. Motor idle, 0·96 E. H. P.; driving machine, idle, 3·9 E. H. P.; planing seasoned oak, cut $\frac{1}{8}$ in. deep by 20 in. wide, 12 ft. per minute, 6·2 E. H. P.

Hand cylinder planer or jointer, size of machine, 24 in.; belt pulley, 4 in. diameter, 5 in. face; speed, 3,200 revolutions per minute; speed of cutting edge of tool, 4,000 ft. per minute; hand feed; motor belted to shaft of tool. Motor, idle, 0·96 E. H. P.; driving machine, idle, 2·40 E. H. P.; planing white pine, cut $\frac{1}{16}$ in. deep by 18 in. wide, 25 ft. per minute, 4·80 E. H. P.

Cylinder planer, size of machine, 24 in.; belt pulley 5 in. diameter, 5 in. face; 2,250 revolutions per minute; speed of cutting edges of tool, 3,105 ft. per minute; power feed; motor belted to shaft of tool. Motor, idle, 0·96 E. H. P.; driving machine, idle, 2·40 E. H. P.; planing pine, cut $\frac{1}{8}$ in. deep, 18 in. wide, 11 ft. per minute, 3·6 E. H. P.; planing oak, cut $\frac{1}{8}$ in. deep, $6\frac{1}{2}$ in. wide, 11 ft. per minute, 3·6 E. H. P.

Boring machine, speed of bit, 375 revolutions per minute; hand feed; motor belted to bit shaft. Motor, idle, 0·96 E. H. P.; driving machine, idle, 1·7 E. H. P.; boring 4 in. hole in seasoned oak, $9\frac{1}{2}$ ft. per minute, 2·3 E. H. P.

Boring machine, belt pulley, 8 in. diameter, 3 in. face; speed, 750 revolutions per minute; hand feed; motor belted to machine shaft. Motor, idle, 0·96 E. H. P.; driving machine, idle, 1·9 E. H. P.; boring 1 in. hole in oak, feed, $3\frac{1}{2}$ in. in 5 seconds, 2·2 E. H. P.; boring $1\frac{3}{8}$ in. hole in oak, feed 1 in. in 7 seconds, 3·2 E. H. P.

Pattern makers' lathe, speed, 888 revolutions per minute; motor belted direct to lathe. Motor, idle, 0·96 E. H. P.; driving lathe, idle, 2 E. H. P.; turning seasoned poplar, 12 in. diameter, $\frac{1}{4}$ in. cut, 8·2 E. H. P.

Carver and moulder, speed of tool, 5,200 revolutions per minute; motor belted direct to tool shaft. Motor, idle, 0·96 E. H. P.; driving tool, idle, 2·8 E. H. P.; cutting groove, circular sector, 2 in. wide, $\frac{3}{4}$ in. deep, $8\frac{1}{2}$ ft. per minute, in white pine, 3·9 E. H. P.

ELECTRICAL PLANT, LONDON CENTRAL RAILWAY.

MESSRS. ERNEST SCOTT & MOUNTAIN have supplied to Messrs. Walter Scott & Company the electrical plant illustrated by the accompanying engravings. In all six engines have been provided, these being fixed at the various stations. Each engine is of Messrs. Scott & Mountain's improved compound central valve, inclosed, self lubricating type, and capable of giving 35 effective horse power with a steam pressure of 120 lb. per square inch when running at a speed of 350 revolutions per minute. The engines are fitted with cylinders of the following dimensions: High pressure cylinder, 7 in.; low pressure, 12 in.; stroke, 6 in. The central valve placed between the high and low pressure cylinders has been specially designed to avoid friction, the valve being balanced, while the arrangement of the ports reduces clearance. The central valve admitting steam to the high and low pressure is worked from one eccentric and rod, the cranks being placed opposite. A special oiling arrangement is provided, consisting of a pump worked from the eccentric rod, and arranged to deliver oil through all bearings under pressure. Suitable doors are provided for the examination of the engine while running or for adjusting brasses. All the bearings are lined with white antifriction metal, and the bearing surfaces throughout are very large. The speed of each engine is controlled by a governor attached to a crankshaft working on to an equilibrium throttle valve, and suitable means are provided so that the speed of the engine can be adjusted while running.

Six dynamos in all are provided, these being used for working the electric locomotives, hydraulic pumps for the shields, and also for lighting purposes. The dynamos are fitted with Gramme armatures, each machine being constructed to give an output of 100 amperes and 200 volts when running at a speed of approximately 700 revolutions per minute. The machines are compound wound, self regulating, and are fitted with adjustable bearings. On reference to the illustration it will be noticed that the height from the bottom of the bedplate to the center of the armature spindle is kept as low as possible to avoid all vibration. The dynamos are mounted upon sliding bedplates with tightening screws and brackets, enabling the slack of the belt to be taken up while running.

The current from the dynamos is taken to main switchboards, on which the instruments are mounted for reading the amperes and volts and distributing switches, and are arranged so that the current is divided into the various circuits, i. e., the locomotive circuit and also the lighting circuit.

Five sets of hydraulic pumps have been provided in all; four sets are similar to that above, and consist of 3-throw hydraulic pumps with rams $1\frac{1}{2}$ in. diameter by 4 in. stroke, arranged to run at a speed of 100 revolutions per minute, driven by an electric motor of 10 effective horse power. On reference to the engraving it will be noted the baseplate forms the tank, which holds sufficient water for filling the hydraulic cylinders, the water being run back into the tank through a waste pipe and used over again. The worm gear consists of a machine cut steel worm and phosphor bronze machine cut worm wheel, the makers having found this type of gear when properly constructed is most suited for this class of driving, and forms a very compact arrangement. A set of hydraulic pumps similar to that above have been provided for working the small shields. The pumps are fitted with rams $1\frac{1}{4}$ in. in diameter by 3 in. stroke, and are driven by an electric motor of 6 effective horse power through machine cut spur gearing.

Six electric locomotives in all have been provided, the locomotives being in accordance with our engraving. The locomotive frame is of cast iron, and carries the electric motor, which is of 35 effective horse power, this power being provided to enable the locomotives to run at a high speed up to 1 in 30 incline. The electric motors drive through machine cut worm gear, the worm being of steel and the worm wheel of phosphor bronze treble threaded and running in an oil bath. The worm wheel is mounted on one of the crank axles, and the axles are coupled together by connecting rods. Each locomotive is complete with over-

STANDARD DYNAMO.

THREE-THROW SIX H. P. PUMP.

ELECTRIC LOCOMOTIVE.

head collecting gear for collecting the current from the overhead copper conductor, also stopping, starting, and reversing switches. On each of the electric locomotives are fitted electric bells and horns.

The electric lighting of the tunnels and surface work is very complete; 16 candle power 200 volt incandescent lamps are used, the lamps being placed in wire protection guards, and suspended from the roof or otherwise as found most convenient. The use of electricity has been found of very great advantage in connection with this contract on account of the much purer atmosphere.—The Engineer.

WIRE BUILDINGS FOR TELEPHONES.

By HERBERT LAWS WEBB.

EVERY large office building that is put up to-day should be fully wired for telephone service. Telephone communication is almost as much of a business necessity to-day as ink and paper, and no modern building can be quite modern, and thoroughly up to date, in which provision is not made for supplying telephone communication to every room. At present, it is true, it is rather the exception to find an office building properly wired throughout for telephone connections, but in a few years the exceptions will be those that are not so wired. The demand for telephone service of all kinds is increasing so rapidly that owners of buildings cannot afford to expose their tenants to the delays and inconveniences incident to running wires through large buildings every time a new telephone service is required. A well designed substantial system of telephone wiring is therefore a necessity in the modern office building, in the modern hotel, in the modern factory and even in the modern club or large residence. The architect who would keep abreast with the requirements of the day cannot afford to neglect this.

There are three requisites that a system of interior wiring should fulfill. These are: 1, that the wires should be suitable for telephone working; 2, that they should be accessible to allow of additions, withdrawals or repairs; 3, that they should all terminate at one central point.

The requirements of clause 1 are not difficult to meet. They demand that every circuit shall be metallic and that the two sides of the circuit shall be twisted together with not less than four twists to the foot. This arrangement of the circuit tends to neutralize the disturbing effects of currents that may be circulating in neighboring wires. As to the size of wire, No. 10 B. & S., insulated to $\frac{3}{32}$ with a good quality of waterproof compound, is sufficiently substantial. But let it be a good quality; beware of cheap insulated wire, for it is the dearest in the end. It is a good plan to have the two wires of the twisted pair of different colors, so that they may be readily distinguished at the ends without the delay of testing out.

Clause 2 means, of course, that the wires should be run in conduits or tubing. The era of inflexible and inaccessible systems of wiring has passed. Every kind of wiring that is done on a large scale should be arranged so that the wires can readily be got at for inspection or repairs, readily withdrawn or added to without disturbing walls, partitions or flooring. Such accessibility and flexibility can only be secured by the use of conduit tubing.

The concentration of all the different circuits at one point is a sufficiently obvious necessity to need no elaboration. The wires should all be taken to a terminal or cross connecting board by means of which connection may readily be made with the trunk lines from the telephone exchange. The cross connecting board will also serve to connect together circuits from different rooms in the event of permanent communication being required between offices in the same building.

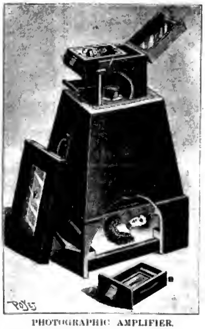
A complete system of telephone wiring laid out in accordance with the general requisites outlined above is a very important and valuable adjunct to the modern office building.—Architects' Electrical Bulletin.

SUBURBAN RAILWAY STATIONS.

THE contrast between Boston's and Philadelphia's artistic suburban railway stations and approaches and the things which do duty as such along most of the lines leading out of New York is as striking as mortifying to the resident of the metropolis. The movement of population at the larger cities is to the neighboring towns, no better illustration of which is found than in the ebb and flow of the tide of nearly 200,000 commuters into and out of New York City daily. Neither Boston, Philadelphia nor Chicago, with incoming and outgoing business populations, compares with New York in the extent to which it attracts commercial, industrial and financial pilgrims daily, yet New York, relatively and absolutely, is worse off than the first two, and hardly any better off than Chicago, as to attractive railway stations at nearby points. There is some attempt by the New York Central and New England lines leading out of New York to beautify suburban railway stations and their surroundings, and across the Hudson the New Jersey Central is conspicuous for the success of its efforts in this direction. The Pennsylvania Railway's artistic railway stations and attractive approaches in the vicinity of Philadelphia have helped to give that company the enviable international reputation it enjoys. In the immediate neighborhood of Jersey City the Pennsylvania has less opportunity to encourage suburban development by beautiful stations in the midst of wide-stretching greenswards and winding driveways than most of the roads running out of Jersey City. Among those from which much is expected, the Delaware, Lackawanna & Western is the most conspicuous offender. Even the Erie, of which much is seldom expected, is building a worthy structure for its patrons at Rutherford, and is soon to put up adequate stations at Passaic and at Paterson. But the Lackawanna prefers, apparently, to cling to the unclean shed which constitutes its station at Newark, and its incongruous buildings and unsightly surroundings at Summit and at Morristown and elsewhere along the line. The hard headed financiers who hold the destinies of the Lackawanna in their hands may be blind to the fact that the expenditure of $100,000 for a new station and the removal of unsightly buildings near it at Summit would increase the value of its own and the town's property many times that amount, and they are undoubtedly oblivious to the fact that an expenditure of enough money at Morristown to create an artistic railway station and in acquiring and improving adjacent property, so as to attract instead of disgusting a new arrival, would redound to the financial gain of the railway as well as of Morristown. But the burden of effort in this direction is not to be thrown upon the railroad company alone. If the residents of the suburban centers referred to do not take enough interest in securing handsome railway stations and approaches thereto, to hold public meetings and use every proper endeavor to secure such advantages, then that public is itself at fault. One would naturally suppose that a railway company, like the lawyer or the merchant, would seek to retain as well as to attract the client, customer or patron, but such a supposition is manifestly absurd with reference to the Lackawanna, which would seem to have searched high and low for all that is unsightly and repellent with which to surround their suburban railway stations or to remodel and utilize as railway stations.—Bradstreet's.

JOUX'S PHOTOGRAPHIC AMPLIFIER.

THE enlarging of a negative is, upon the whole, quite a simple matter, although the operation requires an installation and apparatus devised for the purpose. If a projection lantern be employed, it will be necessary to have a special model that allows no white light to pass, and also to use a condenser that permits of illuminating the negative very uniformly. This is one of the principal difficulties in the work of enlarging by artificial light, the negative to be enlarged being often more strongly illuminated in the center than at the edges. This does not happen with a good apparatus—one that is perfectly adapted to the size of the negative that it is desired to enlarge; but it frequently happens that the operator has a tendency to somewhat force the instrument that he employs, and an apparatus constructed for a $3 \times 3\frac{1}{2}$ in. negative is sometimes used for



PHOTOGRAPHIC AMPLIFIER.

a $3\frac{1}{2} \times 5$ in. one. In this case the results will be defective. From this point of view, the use of daylight is preferable. The installation well made for all sizes of negatives, the illumination is always uniform. On another hand, it is impossible to work at night, and the time of exposure must be varied not only according to the density of the negative, but also according to the state of the sky.

Every medal has its reverse; but, however this may be, it is daylight that has been judged the most practical by manufacturers of small apparatus, and so they have devised special instruments of easy manipulation that permit of operating almost automatically.

We have already described several of these, and now purpose to make known the one manufactured by M. Joux, the maker of the "steno-jumelle."

His apparatus consists of a truncated pyramid, A, upon which is fixed an objective. To the top is adapted a box, B, closed by a cover, V, provided with a ground glass, and which we have here supposed to be open. Just above the objective there is a shutter that slides into the box with slight friction. At the upper part of the box and beneath the cover there is a slide that permits of inserting the frame, C, carrying the negative to be enlarged. This frame has two grooves, which are situated at such a distance from each other that the negative is in focus for a magnification of 5×7 in. when the slide most distant from the objective is used, and of 7×9.5 in. when the nearest is employed. At the base of the box, A, there are two apertures designed to receive a frame with a curtain into which is put the sensitized paper that is to receive the enlarged image. The aperture most distant from the objective is used for dimensions of 7×9.5 in. and the nearest for those of 5×7 in.

The modus operandi is very simple. After the size of the enlargement that it is desired to obtain has been chosen, and a sheet of sensitized paper has been placed against the glass of the frame, in a dark room, the frame is closed and introduced into the apparatus. On another hand, the negative is arranged at the other extremity, as we have already explained. After this, the cover that carries the ground glass and is designed to filter the light and to diffuse it is closed, the curtain of the frame is drawn aside, and the shutter is pulled out. There is nothing to be done now but to point the apparatus toward the sky for a few minutes—from one to ten, according to the negative, the weather and the paper employed. The developing and fixing are done as usual.

The same apparatus may, of course, be used reversibly, that is to say, be made to give small positive images from large negatives. In this case, there are used two frames, D and F, which are represented apart in our engraving.

The small frame, D, has a curtain, and in it (in the laboratory) is placed the sensitized plate that is to receive the positive image designed to be projected. In the frame, F, which is provided with a ground glass, is arranged the 5×7 or $7 \times 9\frac{1}{2}$ negative that is to be reduced. Then each frame is put in place in the apparatus, the apertures into which it is inserted depending, as before, upon the dimensions to be obtained.

After the curtain of the small frame has been drawn aside and the shutter has been pulled out, the large end of the apparatus is turned skyward for a few minutes.

A preliminary experiment is necessary to determine the time of exposure.—La Nature.

SOME NOVEL USES FOR ARTIFICIAL REFRIGERATION.

NUMEROUS special applications of refrigeration have arisen which would scarcely have been suspected until small refrigerating plants were perfected. There are many products, such as oil and chemicals, which are drawn very hot from the stills and retorts, and on which the saving of time by quick cooling more than pays for the cost of refrigeration.

Among these lines of service perhaps one of the most interesting is that of chocolate making. Chocolate was formerly manufactured only in cold weather, when the temperature was low enough for it to be worked and hardened.

A working room temperature of 65° is sufficient for the dipping process and insures the setting of the chocolate when put in the chill room at 45°. If the temperature be much above 65° the chocolate remains sticky and plastic, which is very inconvenient under any circumstances, and absolutely fatal to bonbons.

Cooling coils are placed around the room like steam pipes, but, in addition to this, and of even greater importance, air bunkers are provided, containing ammonia coils, over which the air is forced and cooled. It is then delivered to the room through large galvanized pipes, running across the ceiling, thus providing ventilation for the operatives and the requisite coolness to work the chocolate. The chill room is refrigerated to 45° in the usual way, and opens off the dipping room.

Another one of the many odd uses of refrigeration is in connection with gelatine working. Every one is familiar with the gelatine capsules in which medicine is administered, and will readily understand that difficulty might be experienced in manufacturing such articles in hot and moist weather.

The capsules are formed of sheets of gelatine pressed over steel pins. The cooling must take place rapidly, in order to turn out the product in sufficient quantity, while to insure quality and general evenness of material a proper temperature must be provided.

In one of these instances it was found that about 120,000 cubic feet of air had to be cooled per hour in order to insure an even temperature for the gelatine, and about 100,000 pounds of steel pins per working day had to be cooled from about 90° to 75°. By combining the two requirements and making the blast of cold air cool the pins, both of these results were effected through one operation, requiring only the cooling of sufficient air in bunkers with refrigerating coils. Perfect success was met, and probably in no other way could so useful a result have been obtained so cheaply.

In the tempering of steel or the cooling of other articles in a bath of special composition of such cost that it cannot well be run to waste—as oil or brine—the necessity arises of removing the heat surrendered by the material cooled, thus keeping a constant temperature in the dipping tank.

In the case of saw tempering, a large volume of brine is refrigerated and circulated through the dipping vat. The large reserve volume acts as a fly wheel, equalizing fluctuations of temperature arising from varying rates of dipping, the compressor running continuously.—W. C. Kerr, in Cassier's Magazine.

AREAS OF DISEASE.

IT is a common knowledge that diseases have, as a rule, their local habitations, says the London Saturday Review. Some, like tropical animals and plants, live only in the tropics; some, like consumption, are gradually spreading over the whole earth; others, like leprosy and smallpox, are gradually becoming limited in their distribution, and may actually be tending toward extinction. Again, there are regions to which diseases have never reached. On the summits of high mountain ranges and in the circumpolar snowfields the earth and air and water are as barren of the microbes of disease as they are of animal life. Without question, if Nansen and his companion had been exposed to the same hardships and the same unsanitary conditions in these islands, the lowered vitality of their bodies certainly would have been unable to resist the continual bombardment of germs to which we are all subjected. In a country like Britain, thickly populated for many centuries, and with the freest circulation of population, it cannot be doubted that every yard of surface contains the germs of the more common diseases, and the native of some newer land, brought over here, falls a victim to our plague-stricken soil. By generations of a destructive elimination we have become highly resistant to our native diseases, just as the Gold Coast natives are less susceptible than we are to their own local diseases. But we are not fully protected, and cancer and consumption—two of our common scourges—still take a large annual toll. It may be assumed that both are due to micro-organisms, the microbe of consumption being well known, that of cancer being as yet only suspected. Probably no inhabitant of Britain escapes infection by the cancer organism; certainly none escape infection by the microbe of tubercle. Most of us, fortunately, resist the intruders and are unaffected by the disease.

ELECTRICAL NOTES.

The London Electrical Review has this announcement: "Appointment Vacant.—The Morecambe District Council is inviting applications for the post of resident electrical engineer at £175 (about $875) per annum." This is about the wages of an able bodied hod carrier in the United States.

According to a German authority, turbid beer can be clarified by electric light. It is said that if electric lamps are suspended in the fermenting vessels, the yeasty matters are rapidly deposited with the resinous, albuminous, and glutinous substances that are always present. The result is due to the light itself, not to the change in temperature.

During the convention of the Nobles of the Mystic Shrine held in Detroit, June 7 to 10, what was probably the largest trolley party in the world was made up of the visitors. Sixty-seven open cars were used and 3,050 people took in the ride, the route being around the city and ending at the Water Works Park. The cars were gayly decorated with flags, and the conductors and motormen each wore a boutonniere. Not a hitch marred the trip. The affair was managed by Messrs. A. A. Schantz, G. P. A. of the Detroit and Cleveland Steam Navigation Company.

Berlin now possesses an electrically driven underground railway, says the Electrician. A tunnel 380 yards long and 3 ft. 4 in. below the level of the street has been made by the Allgemeine Electricitäts Gesellschaft to connect their two factories in Brunnen Strasse and Acker Strasse. There are two curves of 50 ft. and 80 ft. radius respectively, and a gradient at one end of the line of 1 in 15. The line is of normal gage and single track. The overhead system is used for conveying current to the locomotives. The latter have two motors, and are designed to draw 10 tons.

The American Machinist extracts from a contemporary a gamut of speeds per second, beginning with that of the snail, which is half an inch, and ending with the following: "Electric current on telegraph wires, 7,000 miles; induction current, 11,040 miles; electric current in copper wire armatures, 21,000 miles; light, 180,000 miles; discharge of a Leyden bottle through copper wire 1-16 inch in diameter, 277,100 miles. This last is the greatest rapidity so far measured." These figures might have more weight and more interest if the methods of calculating them or the authorities had also been given.

The flexibility of the electric elevator machine has recently been most strikingly illustrated at one of New York's newest skyscrapers, now being erected in the lower part of the city. Three electric elevators were installed and put in operation while the building was in the very early stages of construction, this being made possible by securing the current from the street lighting system. Rough cages were first operated, serving as hoists for building material and for the various mechanics. Not only has a great deal of time been saved by the early installation of the elevator apparatus, but so efficient has the freight service been that the hod carriers' work has been largely dispensed with, resulting in a saving of money, but, according to the Electrical World, at the same time bringing forth a strong objection from the Hod Carriers' Union.

Koch, in the Elek. Zeit., thinks it will suffice to run ordinary galvanized iron wires around the top and edges of a house, say in the form of about ten wires, each leading into the ground, to protect it from lightning. If telephone or other wires or gas or water pipes enter the house, they should be connected with this system of lightning wires through suitable arresters when necessary. The platinum or gold points he considers unnecessary. Precht has shown that the issuing of electricity from points takes place so slowly that the points cannot respond to the rapid oscillations of the lightning discharge. The wires may be secured directly to the building; as iron rusts when soldered, all soldered joints should be avoided and the wires should be run in continuous lengths into the ground. The earth connections may be made by simply running short pieces of wires into the ground. The cost of such a system for an ordinary house should not exceed $4 to $5.—Elec. World.

A table taken from the annual reports of the railroad commissioners of Massachusetts and New York for nearly all of the street railway properties shows some interesting facts, says the Engineering and Mining Journal. The table gives the number of cars owned, the car mileage per year, and the cost of the electric power per car mile and per passenger. Of the 19 companies operating less than 250,000 car miles, 4 are obtaining power at a cost of less than 2c. per car mile, 6 between 2 and 3c., 5 between 3 and 4c., 1 between 4 and 5c., and 3 at more than 5c.; of the 5 companies operating over 5,000,000 car miles per year, 1 obtains the power for less than 1c. per car mile, 3 between 2 and 1c., and 1 between 2 and 3c.; other similar figures are also given between these limits. The Brooklyn Heights Company has the cheapest power, 0·86c. per car mile, followed by the Binghamton with 0·94c.; the cost of power for the Massachusetts roads includes repairs and depreciation of the station plant, which is not the case for the New York roads.

In a recent article in the American Machinist, Mr. A. M. Lozier, M.E., of the Bullock Electric Manufacturing Company, says: "When electrical transmission stepped to the fore, even the best equipped factories presented a most inconsistent appearance. Their condition might be compared to two strong iron links of a chain held together by a piece of string, for on the one hand their boilers and engines were of the best and most economical types, and on the other hand their tools or printing presses were compact, automatic and highly efficient. But the connecting link, the means of transmitting the power from the engine to the tool, was a weak one, a great source of waste in power and a relic of conservatism. It is astounding that for years, thousands (indeed, one may say millions) of horse power hours have been wasted in the mere friction load of shafting and belting, without any serious consideration of the matter by mill owners and printers. Records of tests made in over 200 representative factories and printing establishments of this country alone show, as an average, that about 50 per cent. of all the power generated by the engines has been wasted in belt or rope transmission of power."

MISCELLANEOUS NOTES.

Johannesburg, according to the latest figures, has now 136,000 inhabitants, 51,000 of whom are whites. There are 16,265 British, 3,335 Russians, 2,263 Germans, 819 Dutch, 442 Frenchmen, 311 Swedes and Norwegians, 200 Italians, and 648 from other non-African countries; the others come from the Orange Free State and the British South African colonies.

The use of liquid fuel is extending in the mines and mills of the Oural region. It has recently been adopted by the Ust-Katoffski Iron Works, and in the iron works at Zlatoust. At the Miniarski Works, in the Szimski district, oil is now used for heating the puddling furnaces, and for all purposes except in the blast furnace, where charcoal is used.

When the Estienne School was opened in Paris last year Le Figaro discovered the last male descendant of the great family of printers, a printer as all his forefathers had been, and regretted that the name must die, as he had a family of daughters only. M. Estienne is now the father of a boy, whom he has named Robert, who will be a printer, too, when he grows up.

Russia's imperial appanages constituting the domain reserved for the support of the younger branches of the imperial family, which was begun by Emperor Paul I, now comprise 21,000,000 acres with a revenue of $10,000,000 a year. The Department of Appanages is the largest land owner, farmer and wine producer in the empire, and is developing timber, sugar and cotton industries on a very large scale. It is distinct from the private possessions of the Romanoffs and from the state or crown demesnes.

The London Chronicle says: "Between March, 1895, and March, 1897, 187,282 men were dispatched to Cuba, 4,827 to Porto Rico, and 26,622 to the Philippines, making a grand total of 218,731. The losses in Cuba from wounds and disease are set down at over 47,000 men, without counting some 16,000 in hospitals. Statistics are not fully returned from the Philippines, but the absence of yellow fever reduces the rate of mortality. The cost of the Cuban war may be roughly estimated at not less than £45,000,000. In the Philippines the expenses mount up to about £400,000 a month. Apart from this burden the nation has had to pay 78,000,000 pesetas in the shape of substitution money for recruits who have shirked the unpleasant duty of serving abroad. Few of the youths sent home from either seat of war will ever regain sound health, as they joined the ranks too early."

Some French lawyers are trying the experiment of giving legal advice free at the Palais de Justice, on the same principle as medicine is dealt out at dispensaries. The idea is a revival of the Bureau of Charitable Jurisprudence, planned by the Constituent Assembly in 1790, and it has been in operation for nearly two years. There are several departments, each managed by a lawyer of ten years' standing, with two younger men as his assistants. The office is open one morning and one afternoon a week. Last year, from January to December, 1,964 persons applied for advice; 1,600 of them merely wanted answers to some legal questions, 17 were lunatics, and 37 well-to-do people were seeking assistance under false pretenses. The lawyers took up, however, 160 delicate and complicated cases and succeeded in settling 61 of them to the satisfaction of their clients; the other 105 were lost after a trial.

"**The value** of the pearls found during 1896 on the coast of the gulf of Lower California," says Handels-Museum, "amounted to $350,000. Besides, there were, however, also exported 5,000 tons of mussel shells, the value of which was estimated at a further $1,250,000. The pearl fishing with appurtenances forms the entire occupation of the natives, and La Paz, the capital for this trade in the peninsula, exists exclusively upon this industry. Until a few years ago only native divers had been employed, and the greatest depth to which they could dive was thirty-five feet. Upon the introduction of the modern diving apparatus a depth of 180 feet was accomplished, and while formerly the best divers could not remain longer than two minutes under water, a modern diver thinks nothing of staying for two hours at a depth of 100 feet, although at a still greater depth the stay is necessarily shortened on account of the enormous volume of water above. The pearl fishing is mostly a matter of good luck, and this is the great charm which attracts the natives, who are almost without exception born gamblers. It is known that not every oyster contains a pearl, and a really valuable one is only now and then met with. Most of the pearls which are found in the waters of Lower California are so-called seed pearls of a very modest value. The divers do not limit themselves to the pearl oysters, but whenever they come across a rare piece of coral or a new kind of mussel they pocket these likewise."

The gold mines of Cañada Honda are the best known of those in the hill range of the province of San Luis, according to a recent article in the Berg- und Hüttenmännische Zeitung. The gold found at Cañada Honda occurs in a comparatively limited area in the valley of that name, and is formed of the detritus of the gold-bearing quartz from the vicinity of the andesite formation, the metal having been washed down as far as Villa Mercedes, leaving the chief deposits of the denuded material near the original site. The workable deposit has a maximum length of 2,200 ft. by 300 ft. in width, and is covered to a depth of about 30 ft. by a barren layer of black earth, followed by a yellow sandy loam. The gold-bearing deposit (Llampos) contains gneiss, crystalline shale, quartzite and andesite, along with a yellow interstitial loam, and has a depth of about 5 ft. A number of depressions, wherein gold has collected, are met with on the surface of the bedrock, and the latter frequently contains gold to a depth of about 1 ft., probably as a result of mechanical agency rather than segregation. The water supply for sluicing is very irregular, there being a scarcity in the winter and frequently a superabundance in the summer season. In winter the chief work is that of washing the deposit exposed by the summer sluicings, and this is effected by three sluices 20 ft. long, 12 in. wide and 8 in. deep, divided into two parts, the lower portion containing the riffles. Four men and a boy are required for working each sluice, and the average daily recovery of gold is ½ to ¾ oz. per sluice.

SELECTED FORMULÆ.

Colors for Polished Brass.—Mr. E. Ebermeyer has just published in the Zeitschrift für der Chemie Indust. formulas for a number of baths, designed to give polished brass various colors. The brass objects are put into boiling solutions composed of different salts, and the intensity of the shade obtained is dependent upon the duration of the immersion. With a solution composed of:

Sulphate of copper	120 grains.
Hydrochlorate of ammonia	30 "
Water	1 quart.

greenish shades are obtained. With the following solution, all the shades of brown from orange brown to cinnamon are obtained:

Chlorate of potash	150 grains.
Sulphate of copper	150 "
Water	1 quart.

The following solution gives the brass first a rosy tint and then colors it violet and blue:

Sulphate of copper	435 grains.
Hyposulphite of soda	300 "
Cream of tartar	150 "
Water	1 pint.

Upon adding to the last solution:

Ammoniacal sulph. of iron	300 grains.
Hyposulphite of soda	300 "

there are obtained, according to the duration of the immersion, yellowish, orange, rosy, then bluish shades. Upon polarizing the ebullition, the blue tint gives way to yellow, and finally to a pretty gray. Silver, under the same circumstances, becomes very beautifully colored. After a long ebullition in the following solution, we obtain a yellow brown shade, and then a remarkable fire red:

Chlorate of potash	75 grains.
Carbonate of nickel	30 "
Salt of nickel	75 "
Water	10 ounces.

The following solution gives a beautiful dark brown color:

Chlorate of potash	75 grains.
Salt of nickel	150 "
Water	10 ounces.

The following gives, in the first place, a red, which passes to blue, then to pale lilac, and finally to white:

Orpiment	75 grains.
Crystallized sal soda	150 "
Water	10 ounces.

The following gives a yellow brown:

Salt of nickel	75 grains.
Sulphate of copper	75 "
Chlorate of potash	75 "
Water	10 ounces.

On mixing the following solutions, sulphur separates and the brass becomes covered with iridescent crystallizations:

1. Cream of tartar	75 grains.
Sulphate of copper	75 "
Water	10 ounces.
2. Hyposulphite of soda	225 grains.
Water	5 ounces.

Upon leaving the brass objects immersed in the following mixture, contained in corked vessels, they at length acquire a very beautiful blue color:

Hepar of sulphur	15 grains.
Ammonia	75 "
Water	4 ounces.

Photographic Hints and Formulas.—

From Liesegang's Photographischer Almanach.—(Amer. Phot. Jl.)

A New Developer for Transparency and Lantern Plates:

Water	60 ounces.
Sulphite of soda (crystals)	60 "
Metol	½ "
Bicarbonate of soda	3 "
Bromide of potassium solution (10 per cent.) a few drops if necessary.	

Dissolve in the given rotation.

Clearness is the first requisite in a good lantern slide, while in a transparency for decorative purposes a slight veiling of the high lights is not objectionable.

Toning and Fixing Baths for Aristo Types:

Plain Bath—

Water	32 ounces.
Pure gold	⅓ gr.

Acetate Soda Bath—

Water	24 ounces.
Acetate of soda, saturated solution	½ "

Gold enough to tone.

Phosphate Soda Bath—

Water	28 ounces.
Phosphate soda	½ "

Gold enough to tone.

Neutralize with bicarbonate of soda or borax. Bath should be as near neutral as possible, or but slightly alkaline. If toning should proceed faster than five minutes, dilute with water. Use strong bath for cold tones and a weak one for warm tones.

Do not overtone; some red should be left in the shadows. When toned put them in running water or—

Salt	4 ounces.
Water	1 gall.

Wash in a couple of changes of fresh water before fixing.

Fixing Bath—

Cold water	1 gall.
Hyposulphite of soda	6½ ounces.

Fix ten to fifteen minutes. Never use the same twice.

Should a harder surface be desired, add, after pictures have been in the bath ten minutes, from 3 to 6 ounces of the following solution:

Alum	1 ounce.
Water	12 "

Fixing bath should be cold.

THE PROPAGATION AND DISTRIBUTION OF FOOD FISHES.

THE report of the United States Commissioner of Fish and Fisheries for the fiscal year ending June 30, 1896, contains some interesting particulars regarding the propagation and distribution of food fishes in the United States. When the present commissioner assumed charge, especial attention was at once directed to increasing the supply of the commercial fishes of the ocean and inland waters, and the propagation and rearing of certain coarser species was discontinued in order to increase the output of more important ones. The principal fish cultural work in hand was the propagation of shad, and the available force was concentrated at the shad hatching stations at Bryan Park, on the Potomac River, and Battery Island, on the Susquehanna River. Work on the New England coast followed, and the usual provisions were made for collecting lobster eggs at Wood's Hole and Gloucester, Mass. The steamer Fish Hawk was also engaged in shad hatching on the Delaware and afterward in collecting lobster and mackerel eggs on the Maine coast, where she was assisted by the schooner Grampus.

SALMON REARING TROUGHS, CRAIG BROOK STATION, ME.

The result as compared with the preceding year was very satisfactory, 148,000,000 shad, 105,000,000 lobster and 31,000,000 tautog eggs being secured. The scarcity of mackerel made it desirable that the government should endeavor to increase the supply of this valuable fish, and steps were taken in April to engage in the propagation of the species at various points on the New England coast. About 24,000,000 eggs were obtained.

The following stations were operated during the year:

Craig Brook, Me.	Fish Ponds, Washington, D. C.
Green Lake, Me.	Wytheville, Va.
St. Johnsbury, Vt.	Put-in Bay, Ohio.
Gloucester, Mass.	Northville, Mich.
Wood's Hole, Mass.	Alpena, Mich.
Cape Vincent, N. Y.	Duluth, Minn.
Delaware River (steamer Fish Hawk).	Quincy, Ill.
Battery Island, Md.	Neosho, Mo.
Bryan Point, Md.	Leadville, Col.
Central Station, Washington, D. C.	Baird, Cal.
	Fort Gaston, Cal.
Clackamas, Ore.	

There have been distributed in suitable public and private waters, by means of the cars and messengers of the commission, 498,488,208 eggs, fry, yearlings and adults of various fishes. The output of some of the more important species, which is markedly in excess of the previous year, is as follows:

Shad	98,481,500
Salmon	10,845,852
Lake trout	8,996,618
Whitefish	189,740,000
Cod	60,212,000
Flatfish	8,172,000
Lobster	97,079,000

Plants were made in all the States and Territories, and eggs of various species were sent to representatives of foreign governments and fish cultural societies in return for similar courtesies received from them as follows:

Quinnat salmon	95,000
Steelhead trout	75,000
Rainbow trout	125,000
Lake trout	50,000
Whitefish	50,000
Total	395,000

FISH REARING PONDS, CRAIG BROOK STATION, ME.

Further experiments have been made in weaving artificial nests in spawning black bass at Wytheville, the fish ponds at Washington and at Put-in Bay. From the results secured at the former station it is believed that artificial nests may be successfully used and the problem of raising this species simplified. In accordance with previous custom, the use of the laboratory at Wood's Hole was granted to representatives of various colleges for biological study, in order that the commission might be benefited by the results of their researches.

The canvass of the fishing industry of the interior waters of the United States begun in the winter of 1895 was resumed and actively pushed during the entire year and is complete. The inquiry did not cover the great lakes, which were canvassed the previous year, but included all those interior States in which the industry was carried on to any great extent. These fisheries are of considerable economical importance, as in 1894 they employed 11,282 persons, representing a total capital invested of $722,328, and yielded to fishermen a product valued at $1,791,145. Inquiries were also prosecuted by local agents at Gloucester and Boston covering a large part of the offshore fishing of New England, which served the purpose of keeping the commission well informed regarding the condition of the great fishing banks of the coasts of New England, Nova Scotia and Newfoundland. At Gloucester there were discharged by American fishing vessels about 76,631,000 pounds of fish and salt fish, valued at $2,205,000; at Boston the quantity of fish landed aggregated 73,808,000 pounds, having a value of $1,346,000. The combined receipts were thus 150,439,000 pounds, valued at $3,551,000. As compared with the previous year there was a net decrease in the quantity of fish landed at Gloucester amounting to about 3,000,000 pounds, the falling off being principally in mackerel, halibut, cusk and hake, while the receipts of cod exceeded those of 1894 by 5,430,000 pounds, and of 1893 by 8,781,000 pounds. The fish brought into Boston in 1895 weighed 13,637,000 pounds less than in the previous year, nearly all of the important species showing a decrease.

In the spring of 1896 the investigations of the salmon streams of the Pacific coast were planned with the view to select suitable sites for hatcheries, and at the close of the fiscal year this work had been begun and was actively carried on. In addition to the regular annual investigation of the fur seal rookeries required of the Fish Commission by act of Congress, arrangements were made for special studies during the summer of 1895 of the natural history of the herds on the Pribilof and Commander Islands for purposes of comparison with their condition in former years with reference to the means necessary for their protection. The investigations are described in detail in the exhaustive report of Mr. Stejneger, published in the bulletin of the commission for 1896.

The fur seal investigations for 1896 provided for a scientific investigation into the present condition of the fur seal herds in the Pribilof, Commander and Kurile Islands. Dr. David S. Jordan was selected to take charge of the party, assisted by Mr. Leonhard Stejneger and Mr. F. A. Lucas, of the United States National Museum, Lieut. Commander J. F. F. Moser, U. S. N., commander of the steamer Albatross, and Mr. C. H. Townsend and Mr. Joseph Murray, special agent of the Treasury Department, and Mr. G. A. Clark, secretary. The Albatross was detailed by the President to convey the party to Bering Sea, and sailed from Seattle, June 24, with the investigators on board. For a brief description of the trip the reader is referred to the report of the commissioner.

Among other work of the commission were studies of the mackerel fisheries, studies into the condition of the oyster fisheries on the coast of Florida, special investigations as to the extermination of migratory fishes in the Indian River, Florida, etc. The exhibit of the commission at the Cotton States and International Exposition, Atlanta, was considered one of the most attractive features of the Exposition, particularly the aquarium. The commission has continued the practice of turning over to the National Museum collections made by its agents and vessels. The commission also issued a number of bulletins and reports.

Having now described the general work of the commission for the fiscal year ending June 30, 1896, we

TROUT PONDS, NORTHVILLE, MICH.

SELECTING AND STRIPPING RIPE TROUT, NORTHVILLE, MICH.

will take up some of the interesting hatcheries which are described in the report of the commission.

From this report it appears that there was a distribution of yearling fish from the Craig Brook (Me.) station, consisting of 151,676 Atlantic salmon, 12,225 landlocked salmon, 27,763 brook trout, 10,000 rainbow trout, and 1,876 Scotch sea trout. The fish were cared for during the summer in the troughs and ponds shown in our illustrations, and were fed on chopped beef, butchers' offal and maggots. The total cost of fish food for the year, including its freight and drayage, was $513.88. The United States Commission and the State of Maine operated conjointly in the collection and maintenance of brood salmon, and in the maintenance and incubation up to shipment of eggs removed to other stations for hatching. To obtain live fish from the weirs about the mouth of the Penobscot, the following method was employed: The fishermen agreeing to furnish live salmon were supplied in advance with large, fine meshed dip nets, lined with flannel to prevent the chafing of the fish; a car was stationed in every neighborhood, and each fisherman whose weirs were so far from the moorings of the car as to forbid their being brought alongside for the direct receipt of captured fish was provided with a large box in which to transport them short distances. As low water approached and before it became low enough to leave the fish stranded on the floor of the box, the salmon were carefully dipped out and placed in the cars. Once a day the collecting steamer made a tour of the district, taking in tow the cars containing salmon and leaving empty ones in their places. The cars were then taken to Dead Brook, where the fish were released in an inclosure of about a third of a mile up and down a sluggish stream, averaging 3 or 4 yards in width and having an extreme depth of about 6 feet. During the season persistent efforts were made to keep the temperature down in the cars by means of ice, and positively favorable results were at last attained by arranging their interiors so that the water, admitted in a greatly reduced volume, should pass through a cooling compartment before reaching the fish. In the application of this method it was necessary to have a separate boat containing a considerable quantity of ice to accompany the fleet. Notwithstanding the fact that every effort was made to protect the salmon from injury in handling, a great many died in a short time from the effects of bruises and chafing. Thirty per cent. may be given as the ordinary ratio of loss out of those liberated in the inclosure.

Egg collections commenced October 26 and closed November 7. The total yield was estimated at 992,000, but a later computation based on careful measurement showed a take of 1,027,353. Of these, 106,653 were lost. The United States received as its portion 602,700 and the State of Maine 318,003. Of those belonging to the station, 329,000 were distributed, and the remainder were reserved for hatching and rearing. Of the 274,158 fry produced from them, 244,405 survived to the close of the year.

In Michigan fish cultural work has been carried on at the Northville station in hatching trout eggs, our illustrations representing the stripping of the fish for eggs and the trout ponds. During the months of July and August the station force was employed as usual in repairing the ponds, improving the grounds and overhauling and repairing the hatching apparatus. The first consignment of lake trout eggs was received on October 27 and the last on December 5, the total collections amounting to 11,122,000, over 3,000,000 in excess of any previous year's take. Owing to the limited capacity of the hatching house it became necessary to ship 5,750,000 of them. Of these eggs, 4,600,000 were shipped in the green stage and 1,150,000 after the eye spots appeared. From those remaining at the station, 1,295,000 fry were hatched and distributed during the months of April and May, plants amounting to 400,000 being made in Lake Huron, 750,000 in Lake Michigan and 100,000 in the Straits of Mackinac. The remaining 45,000 were distributed to private individuals for stocking inland lakes.

For the cultivation of brook trout arrangements were made for the lease of 4 acres of land on a brook flowing into the Au Sable, a field station was established and the collection of fish commenced on August 20. Operations were continued until November 10, during which time 6,453 trout were caught and confined in a pond prepared for them. During the early part of the season the collections were made with rod and line, but after October 1 a seine was used with excellent results, a 20 foot minnow net bringing in at each haul from 5 to 75 trout. The largest catch in any one day was over 600. The first ripe fish were found on October 3, and by the close of the season 390,807 eggs had been secured. From the experience gained this year, there is no doubt that much better results can be secured, and at reduced cost, as it is unnecessary to establish the station before the end of September. A number of experiments were made during the season in transferring eggs before they were eyed from the field stations to Northville. Fourteen shipments of eggs were made, varying in age from 1 to 22 days, and it was found that they could be moved successfully up to and including the eighth day; between the eighth and the eighteenth days the losses were much heavier, in some cases being as high as 50 per cent. The mortality among the wild brook trout taken from the Au Sable early in the summer was very heavy, and only 233,928 eggs were secured from them. From the domesticated stock 46,710 eggs were taken from 78 spawners. Of 667,445 brook trout eggs obtained from all sources during the season, 75,000 were transferred to the United States Fish Commission stations at St. Johnsbury, Cape Vincent and Duluth; 20,000 were furnished to the Minnesota Fish Commission, and 21,000 to applicants in Ohio. From the remaining stock, 200,000 fry were hatched and furnished in March and May to applicants in Michigan, Iowa, Wisconsin and Ohio, for planting in public waters.

LIVING BAROMETERS.

THE spider is a good example of the living barometer. Close observation of the work on its web castle will soon enable one to forecast the weather. When a high wind or a heavy rain threatens, the spider may be seen taking in sail with great energy—that is, shortening the rope filaments that sustain the web structure. If the storm is to be unusually severe or of long duration, the ropes are strengthened as well as shortened, the better to resist the onset of the elements. Not until pleasant weather is again close at hand will the ropes be lengthened as before. On the contrary, when you see the spider running out the slender filaments, it is certain that calm, fine weather has set in, whose duration may be measured by their elongation.

Every twenty-four hours the spider makes some alteration in its web to suit the weather. If these changes are made toward evening, just before sunset, a fine, clear night may be safely counted upon. When the spider sits quiet and dull in the middle of its web, rain is not far off. If it be active, however, and continues so during a shower, then it will be of brief duration, and sunshine will follow. These various indications may be witnessed and studied to the best advantage in the open air. But you need not always go outdoors to watch the spider barometer. There are few houses where the crafty creature does not find an obscure corner wherein to swing its signboard: "Flies taken in and done for here." Watch these places, and when you see the spiders coming out on the walls more freely than usual, you may be sure that rain is near.

There are individuals who would not keep a stock of spiders about their premises for the express purpose of prophesying the weather from their movements, and the enmity felt by the good housemaid for this particular species of animal is notorious. Those individuals can study the movements of their own domestic animals. Cats and dogs are given to scratching and other uneasy movements on the approach of rainy weather, and their fur looks less bright and glossy. Horses and cattle stretch their necks and sniff the air. Sheep become frolicsome or turn their backs to the wind, and quarrel frequently. Goats bleat incessantly, and leave the hilltops for more sheltered spots. Pigs run uneasily about, carrying straw to the sty, and no longer wallow in the mud and mire. Fowls huddle together in the farmyard with drooping wings, and the air is filled with the clamorous cackle of geese and ducks. Those who live in the country and spend much time in the open air have the advantage of observing the movements of wild animals, and of feeling keenly in their own persons the operations of the changing atmospherical conditions. Moles become more active in digging; stoats and weasels become unusually restless and uneasy; and the hedgehog fortifies his cave against the coming storm with an unfailing provision which has earned for him a most enviable reputation as a weather prophet.

Wild birds make still better objects of observation, because in the "large air" their actions are easily noted. Crows and swallows remain near home when a tempest is brewing; seagulls no longer venture out to sea, but hover over the fields or fly inland when wind and rain are near; swallows fly low and skim the water; and the robin broods melancholy in the bush, or seeks the shelter of a neighboring roof. These are only a few of the many creatures of the fields and the air which enable a man who has eyes to see to forecast the weather during the next few hours. The explanation of all this is to be found in the exceeding sensitiveness of most animals, especially those which are more or less wild, to atmospherical conditions. They are all constantly making forecasts after their own manner, and, as we have hinted, they are far more trustworthy than any devices of man toward this end.

Several ingenious attempts have recently been made to turn this unfailing instinct to some commercial use. A number of very unique living barometers have been put upon the market. The cheapest, and the one which will probably become the most popular, is the frog barometer. A small green frog is found in Germany, which always comes out of the water when cold or wet weather is approaching. These frogs are caught and kept in glass jars furnished with a tiny ladder and half filled with water. The frog weather prophet sits high and dry on the top of his ladder for several hours before a storm, and climbs down to the bottom when the weather is to be fair and clear. Other remarkable weather prophets are leeches, and we have heard of an old meteorologist who adjusted his barometer in such a way that the leeches would ring a little bell whenever a storm was approaching, and would remain silent when the weather was fair or setting fair. These creatures will also indicate the weather in the same way as the green frog referred to. If kept in a jar filled with water, they will climb up the sides when it is about to rain, and gather round the top.—London Standard.

BIVALVES AND TOOTH SHELLS.

THE following are excerpts from a lecture delivered at the Academy of Natural Sciences, of Philadelphia, by Prof. Pilsbry, of that institution.

Among the lamellibranchiata the principal peculiarity is the gills, formed of two plates going down each side of the body. They may be known from all other mollusks by the bivalve shell in which they are closed. They have no eyes on the head and no tentacles. They lack the radula, or hard organ, for grinding the food; while all the other mollusks have this. Lacking this hard part for dividing the food, they live chiefly on infusoria, desmids and diatoms. The sole organ of protection for the bivalves is the shell, composed of two parts, usually fitting more or less exactly when closed. Some of the fishes have jaws strong enough to crush bivalves and swallow the whole animal and digest the contents. Some birds will carry them up into the air and let the shells drop and break, and then eat the contents.

Some mollusca are eaten by star fish; but the method by which the latter gets at them is not known. A number of bivalves are infested by a little crab called oyster crab. It lives in the mantle cavity of the bivalve and obtains its nutriment from the water which is brought in by the bivalve. It is not in any sense truly parasitic on the bivalve.

Aristotle first gave to the oyster crab its scientific name—pinnotheres, because found in the bivalve pinna, abounding in Greek waters.

Most oysters live partially or wholly buried in the mud, communicating with the surface by means of a very long siphon. The head end is always downward; so that they live really standing on the head. The body walls and the gills in the bivalve divide the body into two parts: First, the lower part, called the lower branchial cavity, and the upper cavity above the gills. There is absolutely no connection between these two cavities of the bivalve, except through the gills and through the digestive tract, so that water will not freely pass from one to the other, but has to be filtered through the gills. The gills not only cause a current of water to flow all the time, but also aerate the blood. The same water supplies the food, so that in the bivalve there are always two totally distinct openings, although sometimes there is no organic dividing line between them, the division being made simply by proximity of the mantle at that place; through the lower the water is passing inward; through the upper, it is always passing outward.

The two valves of the bivalve are held together by a hinge along the upper margin, which is more or less of the consistence of cartilage in the fresh specimen, and which, being very elastic and contractile, tends always to keep the valves gaping open. This tendency to keep always open is counteracted by two strong muscles situated at the end of the body, and which, by their contraction, close the valves.

The nervous system of the bivalve is a very simple modification of that of all the other mollusca. There is a ring around the orifice, composed of several ganglia, of which the cerebral is the principal one. The siphons are formed in the simplest manner, by juxtaposition of the two mantles.

In some bivalves the siphon is extremely long, especially in a Pacific coast species—over a yard in length—and it takes the greater part of an afternoon to dig one out, though very edible when secured.

In the astragali the united mantle margins and the siphon have become calcified by the deposit of lime in their surface, and the result is a calcareous tube, having very little resemblance to an ordinary bivalve. At the foot end of the astragalus there are a great many perforations.

Another form in which the siphon is greatly developed is teredo, or the ship worm. Some wood was submerged four years, and was nearly eaten out in that time.

The ship worm first enters by a minute hole, scarcely larger than a pin would make. The eggs, which float in the water, are caught and stuck against the pile, and the animal hatches in this minute hole, and thus perforates the wood, generally boring parallel to the grain, and avoiding running into one another's holes, and two holes seldom being found confluent. Their ravages are found sufficient to destroy most woodwork put into the water in temperate or tropical climates.

Mussels deeply buried practically never remove after once getting themselves into their holes.

The pholads bore into hard rock. The food of the pholas is tough and hard, and by rubbing against the stone and clay and sand, they gradually wear away a hole for themselves.

The pearl oyster has only one muscle. This arises by reason of the decrease of the interior muscle, which is nearest the mouth, and the consequent increase of the other muscle in order to fulfill the functions of both of them.

In the oyster there are a number of other conditions not found in ordinary bivalves. The two valves are rarely equal. This is the result of the fact that the oyster usually lies on one side or stands upright, and is attached by one valve to another oyster or rock or to branches of trees in the water.

Most people who eat oysters do not realize that the rather shapeless mass contains gills, muscles, nerves, digestive and reproductive organs—all the apparatus of a highly complicated living thing. Bivalves are such helpless things that we hardly ever give them credit for being alive, much less for having organs.

It may be interesting to see what the organization of an oyster is. On removing the top valve and the mantle, we find that they have two gills, lying on each side of the body, just within the muscle, and upon removing these, we find in the center the large adductor muscle and the labial palpi (comparatively very large in the oyster) and the digestive system, very much on the plan of the ordinary mussel. The dark portion is the liver. In all mollusca the liver is very highly developed. The mantle is free all the way round in the oyster, not united, and they are entirely without siphons, because the oysters, not boring at all, have no need of any siphons to convey the water to them. Oysters occur on nearly all coasts, and every part of the world has its own particular species.

The European oysters are much smaller than our Chesapeake Bay oysters. California oysters have a copper taste. In South Australia the oysters are as large as a dinner plate. On the coast of Japan I have seen oysters nearly two feet long. From the Loo Choo Islands I have had oysters sent me nine inches long and seven inches wide. One oyster would be enough for a small family.

The good parts of the oyster are largely due to the absence of the foot, which makes the clam so tough and hard; but the oyster, on account of all its life being attached, has the foot rudimentary. In fact, it is reduced to almost nothing, so that the greater part of the animal is simply the soft organs—the only hard organ being the adductor muscle. The foot is always most developed in the bivalves, which use it for digging—such as the razor shell and the river mussels; but in forms living all their lives attached, the foot is reduced to a mere rudiment.

The two parts of a bivalve are, of course, called the valves, being connected by a hinge above. In some forms the mechanism for opening these is an external hinge, as in the ordinary river mussels; but in others, as the beach clam, there is no external conventional hinge, the mechanism being an internal cushion or cartilage.

The accurate closing of the valves is insured by what are called teeth along the margin of the shell. These are interlocking processes which prevent side play and cause the valves, when closed, to close accurately one upon the other. The teeth of bivalves are of several kinds. The most primitive kind are a row of comb-like teeth along its great hinge line.

The interior of the shell also shows a good many characteristic marks. The mantle is the fleshy organ which lines the shell.

TOOTH SHELLS.

The scaphopod shell is simply a tooth, tapering to a

point at one end. The foot is a long organ, somewhat like the foot of bivalves, but very slender. They have a distinct head, in which the mouth is in the center of a row of little lobes or leaflets at the end of the head, and the whole surrounded by very numerous tentacles, with which it catches its prey. These tentacles are knobbed at the summit, but flexible. There is no gill, the blood being aerated simply by the water in its relation to the skin. The whole, general skin serves as a gill. There are no eyes; the ears are present, and the heart pumps arterial blood only. The head and feet are crowded close together; but this is also the case in bivalves.

A scaphopod always reminds me of a man who had a great tie around his body and was pulled by this great tie into a barrel, because of the very close relation of the head and feet. There is no very distinct stomach, and there is a very large and complex liver. The sexes are separate, that is, in two separate individuals, instead of (as in many bivalves) both sexes being united in one individual. The scaphopods live in water from one to two fathoms deep, down to the greatest depths which have been explored so far, some having been brought up from water 3,000 fathoms deep (about four miles). They live in muddy bottoms as a rule, immersed for nearly their whole length in the mud, only leaving the small end sticking upward; and in Oregon and in Washington the aborigines of that coast use the shells of scaphopods for money. The Indians make a sort of rake, by sticking pegs in a board and fastening that on the end of a long stick, and then go along in a canoe and push the stick down in the mud, and these small pegs would every once in awhile catch in the small end of a dentalium and bring them up; and in that way they would capture a large number and use them for money, before banks and the white man's currency replaced them.

The shells of the scaphopod range from two to three inches long to perhaps 1-16 inch for the smallest sort. There are only two principal genera of them, which is also a contrast to the other groups of mollusks. The principal genus is dentalium, in which the shell gradually tapers from a small end to a large end; and the other genus is cadulus, in which the shell is swollen in the middle, and, while tapering most toward the upper end, tapers also toward the mouth end. In cadulus there is also a modification of the foot; it is longer than in dentalium and ends with a disk with crenelated border.

When the animal is digging, it elongates this disk and makes it very much slenderer and more pointed and sticks it down into the mud; and then it inflates it by forcing water down through it, and, by the contraction of the foot, pulls the whole shell downward. That is the general mode of digging of all the dentalia. If one is put on the surface, it inserts the foot and enlarges the end and pulls on the muscle. The muscle is inserted at the foot and is fastened on at the smaller end, so that by its contraction the foot and all the soft parts are retracted into the shell, so that in the two classes of mollusks we have considered this afternoon—the lamellibranchiata, or bivalves, and the scaphopods—we can always distinguish them by the shells—by the fact that in the lamellibranchiata a two-valve shell is always present and in the scaphopods there is a two-valve shell open at both ends.

A NEW CLASSIFICATION OF STELLAR SPECTRA.*

MANY of the recent advances in our knowledge of the constitution of the stars are traceable to Prof. Pickering's revival of Fraunhofer's mode of investigating stellar spectra. The endowment of this research by Mrs. Draper as a memorial to her husband, Dr. Henry Draper, has enabled Prof. Pickering to apply this method in two principal directions. First, a series of photographs was taken on a small scale to indicate the chief characteristics of the spectra of a very great number of stars; second, in the case of the brighter stars, another series was taken with greater dispersion with the view of facilitating an inquiry into the more minute features of each type of spectrum. The results of the first investigation are comprised in the well known "Draper Catalogue," giving particulars of the spectra of over 10,000 stars (Nature, vol. xlv, p. 427), and the research has now been advanced another stage by the publication of the results obtained along the second line of inquiry.

The new series of photographs has been taken with one to four objective prisms of 15° each in conjunction with the 11 inch Draper telescope of 153 inches focal length.

When four prisms were employed, the spectra were 8 centimeters long from Hδ to Hϵ, and with one prism 2 centimeters. Since only the brighter spectra could be photographed with the highest dispersion, some of the more typical of these were also photographed with one and two prisms in order to give a proper term of comparison with the spectra of the fainter stars. In all, 4,800 photographs of the spectra of 681 of the brighter stars north of declination —30° are included in the present discussion. By the use of plates stained with erythrosin the spectra of several stars have been photographed in the green and yellow.

As in all previous work involving considerable numbers of stellar spectra, it has been found that the spectra can be classified in large groups, between which there are intermediate varieties. "Large numbers of almost identical spectra are found, even when several hundred lines appear in each." The description of the spectra accordingly takes the form of an account of typical stars in the scheme of classification adopted, accompanied by tables of the lines which characterize the larger groups. No attempt has apparently been made to assign chemical origins to the various lines, so that the endeavor to arrive at a natural and satisfactory system of classification may be regarded as the most important part of the discussion.

The classification of stars has another object besides that of the mere grouping together of those which have similar spectra. It is generally believed that the various types of spectra represent different stages of stellar evolution, but there are divergences of opinion as to the exact order in which the various types should follow each other. Dr. Vogel still holds, with some slight modifications, to the classification which he suggested in 1874, and believes that all the stars can be arranged along a descending line of temperature. Sir Norman Lockyer, who has adopted the same method of work as Prof. Pickering, and has also obtained large scale photographs of stellar spectra, finds evidence that there are some stars which are getting hotter, while others are becoming cooler, so that the two series of spectra can be recognized.

For the Draper Catalogue a somewhat arbitrary and provisional classification was adopted, but this has not been found sufficient to meet the requirements of the more detailed results which are now available.

Among the stars with line spectra, as previous researches have shown, there are a few sets of lines which occur with various relative intensities in different stars, each set in some degree varying bodily, and the new classification is based chiefly upon the distribution of these sets. As will appear later, the classification adopted by Miss Maury also takes account of the appearance as well as of the positions of spectral lines, and every care has been taken to eliminate instrumental sources of error.

Four distinct sets of lines are distinguished. The first includes the lines of hydrogen and calcium, and the remainder are thus described:

"Another class of lines frequently mentioned comprises those which are characteristic of the solar spectrum, excluding the lines of hydrogen and calcium. They are called 'solar' lines, except when referring to lines not contained in the solar spectrum, in which case they are called metallic lines.

"A third class of lines includes those known as 'Orion lines,' from the fact that they are conspicuous in the spectra of many stars belonging to the constellation Orion. . . .

"Certain stars, such as α Cygni and δ Canis Majoris, have spectra in which the majority of the lines, though probably identical in position with lines belonging to the solar spectrum, differ greatly in intensity, while others apparently are not represented in the solar spectrum. The characteristic lines of such stars should perhaps be regarded as forming a class distinct from those already described."

Bearing in mind these different classes of lines, the new system of classification can readily be understood. Excluding "composite" spectra and bright line stars, "the stars were arranged in an apparently progressive series, which in the present case was made to include twenty-two groups. . . . But it also appeared that a single series was inadequate to represent the peculiarities which presented themselves in certain cases, and that it would be more satisfactory to assume the existence of collateral series."

Three lines of progression are recognized in the earlier stages, and are called "divisions." Stars of division a are characterized by lines having the appearance with which we are familiar in the solar spectrum; that is, they are fine and sharp, if hydrogen and calcium be excluded. Those of division b are uniformly hazy as in α Aquilæ, but otherwise present no notable differences in relative intensity from corresponding lines which are sharp in division a, so that "there appears to be no decided difference in the constitution of the stars belonging respectively to the two divisions." In division c the hydrogen lines are narrow and sharp and less intense than in the other divisions, while several lines, some of which do not correspond with solar lines, are of unusually great intensity; these are especially marked in α Cygni.

Groups and divisions alike proceed by very gradual stages in some parts of the series, and it has frequently been found difficult to assign some of the stars their proper places.

In consequence of the adoption of the term "group," which has been in use for the last ten years in connection with Sir Norman Lockyer's classification, some confusion may possibly occur, as similarly numbered groups include different stars. To avoid ambiguity, it will therefore be necessary, in the case of the first seven groups at least, to specify the system of classification in question. In what follows, the Draper groups will be distinguished by the addition of the letter D to the number where necessary.

Of the twenty-two groups, the first five include stars in which the Orion lines are especially marked; the sixth contains stars intermediate between this type and the first type of Secchi, to which belong the stars in the seventh to the eleventh groups inclusive. The twelfth group is intermediate between Secchi's first and second types, and the stars included in groups thirteen to sixteen are of Secchi's second type. Groups seventeen to twenty inclusive correspond to Secchi's third type, and the groups twenty-one and twenty-two to the fourth and fifth types respectively. Besides these, two unnumbered groups are recognized, one containing composite spectra, apparently resolvable into two or more, and the other including stars of the Orion type which also show bright lines. Nebulæ find no place among the numbered groups, but reference is made to a former paper (Ast. Nach., vol. 127, p. 1), in which it was suggested that the Wolf Rayet stars probably form a connecting link between the spectra of nebulæ and those of the Orion type.

It is not possible within the limits of this notice to indicate the full details of the twenty-two groups with their subdivisions, but the general course of development which is suggested may be briefly stated.

In group I D, of which ϵ Orionis is a type, the hydrogen lines are comparatively faint, while the Orion lines are strong, and "solar" lines are absent. Passing to Secchi's first type, through groups II D to V D, the Orion lines become fainter and less numerous until in the spectrum of Sirius (group VII D) all but two or three are wanting. Meanwhile solar lines have become numerous, and the hydrogen lines reach their maximum intensity. The transition to succeeding groups is very gradual, hydrogen lines thinning out and solar lines becoming stronger. Arriving at stars like Capella and the sun (group XIV D), the intensity of the hydrogen lines is little more than a tenth of that shown in Sirius, and they afterward continue to decrease, but less rapidly, down to the third type stars (groups XVII D to XX D), where they are inconspicuous. In the third type stars banded absorption appears, and becomes more marked in each succeeding group, while the majority of the lines fade out in the later groups. An important feature of the series is the manifestation of extensive absorption in the later groups of second type stars and in those of the third type.

For the present, the series is regarded as ending with the spectra of the third type, stars following the twentieth group not being considered as having a place in the series exhibiting the gradual development of stellar spectra.

Spectra of division c are not found after the thirteenth group, and those of division b disappear still earlier, "so that the series tends to become more uniform as it progresses."

In connection with the new classification, it is remarked (p. 11) that "while it will be generally admitted that the series represents successive stages in stellar evolution, it may still be doubted whether the arrangement beginning with the Orion type, and here adopted, is in fact the natural order. It is strongly indicated, however, by the gradual falling off of the more refrangible rays in the successive groups, by the corresponding increase in the less refrangible rays, and by the occurrence of marked absorption at the close of the series. The comparative simplicity of the Orion spectra and the increasing complexity shown throughout the series lends additional weight to the argument. Finally, the prevalence of the Orion type in great nebulous regions, as in Orion and the Pleiades, indicates very emphatically that stars of this type are in an early stage of development."

It will be seen that the supposed evolutionary series has been arrived at without reference to temperature considerations. Nevertheless, a gradual reduction of temperature as the series progresses is suggested by the diminishing intensity of the more refrangible rays, so that, in the main series at least, the order is in all probability one of gradually reducing temperature.

As already remarked, the stars of Secchi's fourth type have been omitted from the supposed evolutionary series of spectra, for the reason that the few lines photographed "have not yet been identified with those of other classes of stars, owing to the total dissimilarity of the spectra." This dissimilarity is stated to extend to the yellow part of the spectrum, and is difficult to comprehend in the light of the more recent results obtained by Dr. McClean, who has shown that the spectrum of 152 Schj contains many lines which are apparently identical with lines in the spectrum of α Orionis (Monthly Notices, vol. lvii, p. 8). The existence of carbon absorption in the solar spectrum, however, is of itself, as Lockyer long ago insisted, a sufficient connecting link between stars resembling the sun and stars in which carbon absorption is predominant. A classification which excludes these stars from the evolutionary series cannot, therefore, be regarded as final.

It is perhaps unfortunate that the new classification was adopted prior to the discovery of terrestrial sources of helium. Many of the "Orion" lines are now known to be due to this gas, but not all of them, so that these lines may be subdivided into groups. In the preface to the volume Prof. Pickering remarks: "As the investigations were made several years ago, they could not take account of the recent discoveries respecting the spectrum of helium, which, if known at the time, might have had an important influence upon some of the conclusions. Such modifications could not now be introduced without practically rewriting the treatise, which is therefore published without change. A discussion of the relation of the spectra of stars of the Orion type to that of helium has, however, been made, and is contained in the supplementary notes."

The question of classification, however, is not the sole feature of interest possessed by the spectroscopic work at Harvard. Besides this, there are several tables which give the wave lengths of the lines depicted on the photographs, a general catalogue of the spectra, and copious remarks on the spectra of individual stars. In the case of the composite spectra it has been noted that in all but one, o Andromedæ, the spectrum of the earlier type was the fainter. The peculiarities of the spectrum of γ Cassiopeiæ, already recorded by Lockyer (Nature, vol. li, p. 425), have been fully confirmed, and the additional fact observed that the entire region of the spectrum from λ 4154·7 to 3957·1 appears brighter than the rest of the spectrum, although the brightening is not homogeneous. The possible importance of this feature is suggested by its occurrence also in stars of the first two groups of the new classification.

The complex phenomena in the variable spectrum of β Lyræ are fully detailed, and the composite character of the dark line spectrum detected at Kensington by Sir Norman Lockyer receives independent confirmation. It is concluded that "the bright bands accompany a spectrum approximately of group IV D (e. g. γ Orionis), which oscillates periodically over one of group VII D, division c" (e. g. η Leonis), a result which agrees very closely with Lockyer's conclusion that the two dark line stars were not very unlike γ Orionis and β Orionis. It is pointed out that the supposition of a system of three bodies explains most of the spectral phenomena of β Lyræ, but not all of them, and the rapid and complex transformations require to be continuously followed before a complete explanation can be given.

While fully aware of the difficulty attending the satisfactory reproduction of stellar spectra, we think the value of the volume would have been greatly increased by some attempt to give copies of photographs of as many as possible of the typical stars. Without such reproductions the classification can scarcely be adopted by others taking up the work unless photographs of all the typical stars are first obtained. In spite of this drawback, the volume is a magnificent contribution to celestial spectroscopy, and will be of the greatest value to those pursuing similar investigations. Prof. Pickering and his assistants are to be congratulated upon the excellence of this additional contribution to the Henry Draper Memorial.—A. Fowler, in Nature.

Paris' monumental Alexander III bridge to connect the esplanade of the Invalides with the Champs Elysees, is causing trouble. It was to be 180 ft. wide, but the engineers' estimates were so much below the actual cost that it will be only possible to build a bridge of half the width with much cheaper material for the money voted.

* Spectra of bright stars, photographed with the 11 inch Draper telescope as a part of the Henry Draper Memorial, and discussed by Antonia C. Maury, under the direction of Edward C. Pickering. (Annals of Harvard College Observatory, vol. xxviii, part 1, 1897.)

THE PIRATES OF MOROCCO.

NOT a single year passes that Morocco does not attract the attention of the civilized world in a disagreeable manner. The entire cost of Morocco is feared and avoided by ships of all nations, for piracy of the most unrestrained and boldest kind is always practiced there, one of the most dangerous points being Cape Tres Forcas, which extends far out into the sea. What difference does it make if Spain has garrisoned Melilla? Spanish power is effective only within gunshot. In the great bay that extends from here to Atalaya many sailing vessels have disappeared without leaving a trace. It is always the same story: a vessel coming from the West at night went too near the shore and was detained there by one of the frequent calms. In such a case only an opportune breeze could help it, unless a Spanish or English gunboat happened to pass that way. As soon as a helpless boat is discovered by the Riffians who are always on the lookout, smoke signals are lighted on the high points of the coast to call the bands together, and then the ship can only await an attack by the bold pirates armed to the teeth who row out to it in their boats.

The following incident shows that the robbers do not always have an easy time. In the latter part of the seventies the Marseilles brig Jeanette went to Senegal with forty-two Italian workmen. They were weather-beaten fellows, mostly Calabrians, and each one was armed with a revolver and a knife and they carried their tools, which were flat axes with long handles. There was also a good little cannon on board. Adverse winds forced the captain out of his course, and one morning he found himself under the rocky coast south of Mogador. About ten o'clock the first pirate boats were close to his vessel. They were received by a hail of revolver balls and the cannon did good work. Two of the boats were sunken and the brown mob tried to get out of the dangerous neighborhood of the brig by swimming. The long handled axes proved very useful when an attempt was made to board the vessel. The whole battle did not last ten minutes, for the boats hurried away to land, followed by the shots of the victors, who were soon after helped away by a favorable northeast wind.—Illustrirte Zeitung.

SMOKE SIGNALS OF RIFFIANS ON THE COAST OF MOROCCO.

DRAWN BY RICHARD FUCHS.

MODERN LOSSES IN BATTLE.

COMPARE the slaughter in Napoleon's campaigns with the worst within living memory—with Gettysburg and Antietam, in the American civil war; with Königgrätz, in the Austro-Prussian war; with Sedan and Metz, in the Franco-German war, says a writer in Chambers's Journal. At Jena, in 1806, the Prussian loss was 21,000 out of a total of 105,000, and the French 19,000 out of a total of 90,000—that is to say, 40,000 casualties out of 195,000 engaged, or, roughly speaking, one in five. At Eylau, in 1807, the Russians lost 25,000 men out of 73,000; the French 30,000 out of 85,000—that is, for both sides, the appalling proportion of one to three! At Wagram, in 1809, the Austrian loss was 25,000 out of 100,000; the French 23,000 out of the same number. At Aspern, where Napoleon suffered his first defeat on May 21 and 22, 1809, the carnage was still greater, for the French lost 35,000 men out of 70,000—one-half their number—and the Austrians 20,000 out of 80,000. But even this awful butchery pales before that of Borodino in the Moscow campaign, for on that field the French left 50,000 dead and wounded out of 132,000 engaged, and the Russians 45,000 out of the same number—95,000 men slain or mutilated out of 264,000!

Now, the only battle in the latter half of the nineteenth century which can compare with Borodino in slaughter is that of Königgrätz, or Sadowa, in 1866, which ended the Austro-Prussian war. Out of 400,000 men engaged, 50,000 were killed or wounded—40,000 Austrians and 10,000 Prussians—one in eight only, as against one in three.

The most sanguinary battle in the American civil war was that of Antietam Creek, fought between McClellan and Lee on September 17, 1862, when, after repeated repulses, the Federals compelled the Confederates to retreat. Out of 100,000 men engaged, 26,460 were left on the field—the Federal loss being 12,460, and that of the Confederates 14,000; and that, remember, was before the era of breechloaders. At Gettysburg the combined losses were 43,000; but the number of men engaged was nearly double, and the proportion, therefore, was not quite so great as at Antietam.

Take, again, Leipzig and Waterloo, and contrast them with Sadowa and Sedan. At Leipzig the French lost 60,000 men out of 160,000, and the Allies 42,000 out of 288,000—102,000 out of a total of 348,000—more than double the ratio of Sadowa. Then at Waterloo the losses of the Allies amounted to 22,976 out of 83,000, and those of the French to upward of 30,000 out of 73,000—in other words, one man out of every three that fought that day was either killed or wounded. Now, at Sedan, under the awful crushing fire of the German guns, the French lost 30,000 out of 150,000 before they surrendered—a far smaller proportion than at Waterloo; while the Germans stated their losses at 3,022 killed and 5,909 wounded, out of the 250,000 brought into action.

These facts and figures seem to us to prove conclusively that war is no longer so murderous as it was. The alteration in tactics and in the formation of troops attacking has counteracted the superior precision and range of modern firearms. The shell, though its moral effect is greater, is not so destructive as the round shot, grape and canister of the old days playing upon troops advancing in line or column. The magazine rifle, incalculably superior in accuracy and penetrating power to the old Brown Bess, is not so deadly in its effect; for when it fails to kill outright, the wounds it inflicts with its tiny projectile are not nearly so ugly and crippling as those of the old spherical bullet, which smashed where the other glances off.

THE RELATION OF HYPNOTISM TO THE SUBCONSCIOUS MIND.*

By GEORGE E. BILL, M.D., Harrisburg, Pa.

THE subject which it has been thought fit to discuss with the society at this time is one believed to be of very great import and latitude in the art and practice of medicine. So evident must this be to the thoughtful mind, that it would seem impossible, in the time allotted by the custom of the society, to more than enter the boundary of a field of inquiry the meaning and possibilities of which are so vast. Therefore only one phase of the topic will be emphasized—the subconscious or subjective mind.

The bald definition of the word hypnotism, strictly speaking, is the artificial production of sleep; but the tendency of the present is to extend its meaning, in order to include the various phenomena to be noted under the head of mesmeric, magnetic or fluidic hypnotism, physical hypnotism, and suggestive hypnotism. These three forms may be used singly or together in medicine.

While there have been, in every epoch and in all climes, students and investigators, renowned or otherwise, in this broad domain, there is no basic fact observable in all their research which they themselves understood as capable of inherently formulating a working law explanatory of hypnotic phenomena. Mesmer formulated his theory of animal magnetism, but his methods savored of charlatanism to the uninitiated, and, apart from his manipulations and their undoubtedly curative effect on disease, no scientific cause could be discovered at that time, except as ascribable to the imagination of the patient.

Braid, by his discovery that fixity of vision or fixed attention induced hypnosis, recalled the desire of the medical world to a further investigation of a tabooed study; but because the various phenomena therein unfolded could be attributable to physicism it was thought that a final quietus had been put upon the claims of Mesmer. As you know, in more modern times, however, there have arisen two schools of hypnotic research—Nancy and Paris. Both adopted somewhat the method of Braid, but to the school of Nancy belongs the honor of first placing the study upon a proper basis in science, and of formulating a law. The school of Paris holds that the various phenomena of hypnotism pertain to neurosis, a conclusion obviously not always correct. Nancy, on the other hand, asserts that hypnotic phenomena pervade the most absolutely healthy organism. It is questionable if both together have not evolved laws of equal value out of the chaos obtaining in the times previous to their origin. Nancy has formulated the great law of suggestion, which underlies all actual scientific progress in the domain of hypnotism. On the other hand, the great name of Charcot and his gigantic labor have caused to be brought prominently before professional recognition and study that almost unknown realm, the subconscious mind. It is impossible to clearly perceive that the one is of value without the other—viz., the law of suggestion and the subconscious mind. Both are of profound and equal importance, neither can do without the other, and both work together in both subject and operator, controlled or controller, in every hypnotic séance. Various are the means and methods employed to induce a condition of hypnosis. The loud command, the flashing mirror, the bright light, the forward or upward fixity of vision, the magnetic pass, the revolving chair, all have for their aim the subduing of the conscious objective mind, which cannot per se be hypnotically influenced. It is to this last fact that it is particularly desirable to call your attention, viz., that it is what Thomson Jay

* Read before the Dauphin, Pa., County Medical Society, January —, 1897.—From the New York Medical Journal.

A MERCHANT VESSEL ATTACKED BY RIFFIANS OFF THE COAST OF MOROCCO.—DRAWN BY RICHARD FUCHS.

Hudson so aptly denominates as the subjective mind, existent in all sentient life, that is always influenced by the law of suggestion, either orally or mentally expressed, and not the objective mind, for the latter cannot be so influenced against its reason. This law of suggestion, so happily discovered, applicable alone to the subconscious mind, and a third fact in hypnotism, *telepathy*, to which your attention will again be called, explain as nothing else can the various phenomena of hypnotism. They are of fundamental value and pervade the whole question of hypnotism in medicine, and are of transcendent therapeutic import. As far back as the student can penetrate, a duality of mind has been recognized by the profoundest thinkers, and it would appear that modern research only emphasizes this ancient division as true.

The more commonly accepted division is known as the conscious and subconscious mind, but the most apt and most natural and distinctive phraseology, since it better accords with various symptomata of disease, would seem to be that of Hudson, who adopts as terms of distinction the words subjective and objective. He says, in effect, that the objective mind exercises its functions with its objective surroundings through the media of the special senses, and is that part of the mind necessarily connecting man in his entirety with physicism. By reason of its objective education it enables him to exist within his physical environment and its "highest function is that of reasoning." *

"The subjective mind takes cognizance of its environment by means independent of the physical senses. It perceives by intuition. It is the seat of the emotions and the storehouse of memory. It performs its highest functions when the objective senses are in abeyance. In a word, it is that intelligence which makes itself manifest in a hypnotic subject when he is in a state of somnambulism." †

The distinction herein expressed offers to your reader the best explanation, in its applicability, of the universal value of the law of suggestion, in the various phenomena of disease. It would seem on profound thought that the subjective mind does, as Hudson asserts, "preside over the emotions and functions of the body," and as a corollary it may be added that it also controls the action of the sympathetic, if measurably so in the male, still more so in the female, by reason of her greater richness of sympathetic endowment; for in the deepest hypnotic stages the female observes through the solar plexus, the male through the pineal gland and medulla oblongata.

Now, it is most instructive and most curious to observe that no physician and no patient are thrown into each other's contact in any walk of life, lay or medical, without these bases of hypnotism unconsciously becoming apparent, and it is this fact, of such wide significance, of such universal bearing, from the beginning of medical times until now, that the medical profession as a whole has either ignored, has been unconscious of, or has even unconsciously used in therapeusis. It is even illustrated in the placebo. That this is eminently true springs from the fact that the physician's attitude, his entire status, public or private, is one of command, of direction, of leadership, while that of the patient is one of submission to an ill, an attitude born of fear, which is an inductive hypnotic element of itself, a condition of entreaty that he be better, of hope that he be aided, of faith that he be cured. This obvious and suggestive fact in the above status being of such pregnant importance, how can we not observe then in this very condition of society a therapeutic buckler capable of fending the arrows of disease, functional or organic? Why, then, should the physician shoot the envenomed shaft of ridicule against so potent a shield from disease as hypnosis? If hypnotism has been synonymous with quackery, it should be no longer so regarded by the medical profession.

* T. J. Hudson. The Law of Psychic Phenomena.

† Id. opus, page 29.

It has been found that there are in the main two general divisions of hypnotic effort. One makes use of the means above noted for its induction, and always presupposes a concentration on the part of the subject and operator, and demands the entire recognition of the operator by the patient and oblivion to all other externals, and is the form of hypnosis in most general use. This form demands also the conscious surrender of the subject to the objective will of the operator, and is objectionable therapeutically, because its practice leads to vacillating volition, except in selected cases, embraced under sexual perversion, alcoholism, morphinism, and criminal impulse.

There is another form, however, which can be more widely employed with benefit to the majority of patients with no harmful results to their objective will power, and with increasing aid to the physician in controlling the symptomata of disease and emasculating the subjective mind of the patient from its bodily environment of suffering. This form of hypnosis demands complete relaxation on the part of the operator as well as the subject, and by reason of the universal status of the patient and physician, above noted, can be the more generally used and with more far-reaching results. In it there is no subtending of the will, no exhaustion on the part of the patient or operator. It is that form of hypnotic effort demanding no fixity or tension of will power, and depends only upon constant iteration and reiteration of suggestions, oral or mental, of the directing mind of the operator upon the subject. It yields most brilliant and oftentimes most astonishing results, and depends upon a fact in psychism denominated as telepathy. Telepathy * is defined as "the power of one mind to communicate intelligence to another otherwise than through the recognized channels of the senses." That this faculty is inherent in man is no longer a matter of supposition, for it is universally prevalent, and is of as much value in hypnotism as the law of suggestion and the subjective mind. It is through the medium of telepathy that the subjective mind and the subjective symptomata of the patient are recognized. Now, it is to be observed that symptomata of suffering on the part of every patient are known as subjective and objective. Ordinarily objective symptomata are easily noticed as disturbances in bodily pulse, temperature, coloring, secreta, excreta, growth or shrinkage, and means are adopted for their amelioration or effacement. But the subjective symptomata are but little commented upon, and while they may claim the paramount attention of the patient in the gamut of suffering, their verbal or oral announcement is too often ascribed to the nervousness or the imagination of the patient, and too often, therefore, disbelieved by the practitioner. Means adopted for the dissipation of the objective symptoms very often efface the majority of the subjective, but not invariably. If disease symptoms, subjective or objective, are dependent, as it would seem, on disturbances in the equilibrium of nerve action between the cerebro-spinal and sympathetic systems, then these oscillations in nervous energy would account for very many of the subjective symptomata complained of. It is at this point that the aid of the nervous force of the operator, through emphatic and confident oral or mental suggestion, can influence and direct the perverted nervous force of the sufferer and lead it back to the wonted channel of health by commanding the subjective mind to resume its proper control of body function. If the telepathic ability of the operator is complete through training, the vast majority of the subjective symptomata of the patient are easily enunciated by him to the patient, the expectant attention of the latter is closely held, his astonishment, delight, and sometimes fear are aroused, and the confidence of both subject and operator is gained. The amount of information culled by this method is often surprising, as to the ætiology of the patient's condition of ill health, its amount, and the tendency therein toward recovery or death. Of course, the various aids of an objective training are to be employed, such as physiognomical indications, vocal tones, ocular expressions, and an objective examination of the patient is to be always insisted upon, in order to objectively verify the clews obtained in a subjective diagnostic or prognostic reading. Very often the disappearance of this or that symptom can be predicted even to its exact time. This prediction involves, of course, oral or mental suggestions, and at times no one is more astonished at the outcome than the operator himself. It is not always necessary to be within vocal or visual distance of the subject to successfully launch a therapeutic suggestion, nor is it requisite to know or to have met the subject even. Personally, this observation has been proved in actual practice, a remarkable example of which will be presented. To summarize, it may be said that hypnosis takes cognizance of—

(a) The law of suggestion.

(b) The existence of a subjective and an objective mind.

(c) The fact of telepathy—all of which factors are universal; and last, though possibly not least, of—

(d) A medium of communication.

What the latter is, what it consists of, has not yet nor will it be distinctly formulated until the laws of dynamics have been irrefutably settled and agreed upon; but the suggestion is offered that this medium of communication may be something analogous to, if it is not, interplanetary ether. If, as is supposed, that interplanetary ether offers the only reasonable medium for the transmission and transference of light, heat, electricity, or magnetism, from their primary sources in physicism, perhaps it may, indeed, be the manner and way and medium of the transference, broadly speaking, of psychism from point to point or along any distance of greater or lesser extent; for it would seem that this interplanetary ether pervades all things and entities and forces in this universe.

It is customary to adduce a series of cases in actual practice illustrative of the topic discussed. It is ex-

* Thomson Jay Hudson. A Scientific Demonstration of a Future Life.

tremely odious to your reader, by reason of the personality involved in a subject of this nature, to follow the usual custom, since a proper personal modesty shrinks from such an exposure; but, while there is nothing in therapeutic results in the main extremely novel to one who habitually and scientifically studies the phenomena of psychism, yet it may be wise to cite one case in point, since it illustrates so remarkably the power of telepathic suggestion on the subjective mind of the mother of one of our local physicians who was ill unto death, and whose condition of illness, by reason of her age and disease, precluded all hope of recovery by ordinary therapeutic means. This case, indeed, bears corroboration in every essential detail, and through professional desire of my confrère is allowed to be discussed. At the outset it must be said that conversational personalities must be indulged in for purposes of illustration.

On a Thursday evening last summer, about 6:45 o'clock, my colleague called and announced that his mother was dying of gangrene of the right foot. Two weeks previously he had told me that there had developed in the joint of the large toe of her right foot an abscess resulting from a shoe pressure on a bunion, and had sought advice therefor, and also said that she had suffered some years from diabetes mellitus. Here was a case presenting grave constitutional and local lesions. He stated that the local lesion had involved all of the toes, which had turned black and had withered, and that there was a most offensive, tough, and deep slough of the upper portion of the foot, extending to the ankle; that there was an intermittent pulse, atheromatous arterial condition, stupor, anorexia, nausea, no thirst, and a constant desire to die. Her age precluded an operation, as she was of too low a vitality to override such a procedure. "Could I go with him to see her on Saturday."—"Yes; but of what avail, since you think that death is imminent?"—"I don't know, but I want you to see her at all events."—"Does she suffer any pain?"—"No; that is just the trouble. She betrays no reaction, and, being so, I consider the case hopeless."—"If we could bring on a reaction of her nervous system," I tentatively suggested, "and arouse her with pain, without additional shock, perhaps something could be done."—"That is just the point, but I do not see how you can do it." This last remark of his gave me a clew to follow in hypnotism. "Where does your mother live? How far from here, and in what direction?" He pointed out the direction and told me sixteen miles, and her place of residence. "Are you willing that I try hypnotism on your mother, for I have an idea that it may do her some good?"—"Yes; but you will have to wait until we go Saturday, won't you?"—No; there is one way we may reach the patient."—"What is that?"—"Telepathy," I answered. Thereat he laughed outright. This nettled me. "Fix your mind on your mother. Get her image mentally impressed as you last saw her this afternoon, and I will not only describe her appearance, face, and position in bed, but the room, and its location and surroundings." He laughingly did so, saying he was ready. In all, save one particular, the patient and locale were correctly described. This assured me that the way was open for success. "Now, give me your hand. To get here to my office you travel in such a circuit and such a direction. It will only be necessary for me to retrace your steps to get there in mind."—"Now, what time is it?"—"Quarter past seven."

At once, with all the power I could summon, and retracing in my mind the path he had taken to come to my office from his mother, I launched upon the subjective mind of the patient the suggestion that she should at once suffer pain and continual pain in the right foot, and that her bodily functions should be restored. We took the time, and agreed that we would question the patient's husband as to the probability of pain occurring near 7:15 o'clock Thursday evening, and whether she suffered more pain from that time up to Saturday on our arrival than she had previously exhibited. The doctor left skeptical, but I persisted in saying that I believed the experiment would be a success and that we would find that she would complain continually, while awake, of the pain. On our arrival the father told us she was worse. "Has she suffered much pain?"—"Oh, yes."—"When did the pain come on?"—"Somewhere between seven and eight o'clock Thursday evening, but nearer seven than eight." Getting bandages and material ready, the father, the doctor, and myself entered the room, and with no especial care and unnoticed by the patient. She lay in a stupor on her left side, her back toward us. The father stood at the foot of the bed, the doctor next at the side, and I near the head. I asked the two gentlemen to join hands, and the father to extend his right hand over his wife's foot. "Now, when I am ready, please notice what you both feel and observe the patient." I mentally, emphatically and confidently, commanded the patient to suffer pain, and that her subjective mind should resume control of her functions, that she should get well, and commanded aloud. "Now suffer pain, pain, reaction." The father felt a shock, the doctor nothing, the mother at once turned on her back with the cry, which I can never forget, dramatic in its intensity, "Oh, what are you doing that you make me suffer so much pain? I can't stand it! I want to die!" Her foot and limb twitched spasmodically with the agony she was suffering. "What have you to say now, doctor, to this form of hypnotism and its effect?"—"I don't know, it is beyond my understanding." The father wonderingly exclaimed, "It is mighty strange. It is wonderful." So far I was satisfied, but when I saw the foot unbandaged and recognized the gravity of the case, my objective training through my objective mind said: "No, she cannot recover." My subjective mind said: "You must gather courage and not yield to the autosuggestion of your objective mind, or she will die." While the foot was dressed I stood at the foot of the bed and mentally and orally commanded that the foot should freely discharge pus until we returned on Monday. As we were returning home the doctor asked: "Well, what do you think? Is she going to get well?"—"My objective training and experience reply No, but if we find on Monday that the foot discharges pus I shall have more hope. My subjective mind assures me, however, that she will get well, against all reason." On Monday the father said: "The foot has discharged more pus between Saturday and to-day than during the previous two weeks, but she won't take my medicine. She says it is a sin to keep her alive when she wants to die and get rid of so much pain."

The difficulty in treating this case hypnotically lay in the fact that the patient, through her own autosuggestion that she would die, strongly militated the suggestive command of the consultant that she must get well whether she wished it or not, and was an autosuggestion that had to be continually fought by your reader throughout the entire conduct of the case. Her mind was affected through the double lesion and the toxæmia, and she has no recollection of the events and symptoms that marked her illness. For several long weeks three weekly visits were made, when gradual hypnotic control was gained over the patient, and the continual, emphatic, and confident suggestions were made that she should recover, and enjoy the rest of her life in comfort. I am assured by her son that she has greatly changed in appearance, that she enjoys life, and that the sugar has markedly lessened. The contour of the foot is restored, with the exception of the loss of all the toes except the big one.

This case illustrates the possibilities of hypnotism, wherein one had not the normal waking intelligence of the subject on which to more easily hypnotically operate, and no objective mind to help the operator; but it shows, indeed, the paramount importance of the subjective mind in hypnotic effort, evidences the existence of telepathy, and indicates, through the path originally taken to launch the initial suggestion, that there must be a physical medium of communication between mind and mind apart from the media of the special senses; for your reader had never seen the patient, the village, nor the road to the room in which she lay ill unto death.

It must be emphatically stated that the reader does not believe in marvels or modern supernaturalism, but on the contrary does assert that there is always a cause for a therapeutic result, and that there are laws established on a scientific basis capable not only of explaining therapeutic results in hypnotism, but also that there are facts which should establish medical hypnosis on such natural, physical, and mental grounds as to forever debar all ridicule, surmising, or odium from a field of medical research which promises such rich results in the future to therapeutists.

The complex man, being composed of mind and matter, cannot be successfully treated either by drugs alone or suggestion alone; but in this age of sordid materialism there are entirely too great claims made for physicism to the exclusion of psychism, which dominates, it must be concluded, the former.

SMITH'S IMPROVED METHOD OF GRAFTING.

This method of grafting is recommended for fruit or other trees, in the orchard and garden, and especially

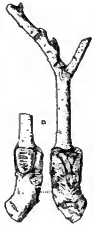


Fig. 1.—An Old and Defective Method of Rind Grafting.

in exposed situations. The scion has a threefold grip of the stock or branch it is placed upon, and this is covered during the first year by the union. The method has been tested in Shropshire and neighboring counties, from my instructions, and has proved a success during the last three years, a vigorous growth having always followed. It can be employed upon stocks varying in size from half an inch to an inch and a half in diameter, and scions may be made from wood one or two years old in the case of fruit trees.

Fig. 1 represents an old mode of rind grafting, the defects of which can be seen at the place of union. Figs. 2 and 3 illustrate the preparation of stock and scion for the method that I advocate—in the one case upon a small stock and in the other upon a larger one. In Fig. 4 the graft is shown when completed and waxed,

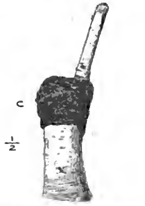

Fig. 4.—A Completed Graft—New Style.

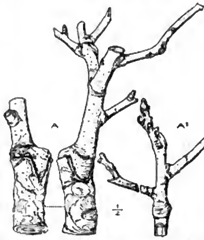

Fig. 5.—Method of Grafting Recommended—Showing the Graft after the First Year's Growth.

and in Fig. 5 is illustrated the effect of one year's growth after the grafting has been done. It will be seen to offer more than ordinary resistance against the wind.—Robert Smith, Horticultural Instructor, Shropshire County Council, in the Gardeners' Chronicle.

THE SIGNIFICANCE OF HOLES IN ARCHÆOLOGY.*

Even now, at the close of this nineteenth century, people, and those not by any means the most ignorant, continue to hoard lucky money—that is, coins in which a hole has been bored by unknown hands. To find or to receive such a coin means good luck far beyond its intrinsic value, for the luck is not so much in the money as in the hole. In this article I propose to show that this present day harmless, but apparently unmeaning, superstition has its root in necromancy or ancestor worship, and can be traced back in various forms, but always in connection with "medicine"†—that is, witch-

* Condensed from an interesting article by Mr. A. W. Buckland, F.A.I., in the Antiquary.

† Throughout this article the term "medicine" is used in the Shamanistic sense, being equivalent to witchcraft, as employed in healing ceremonies by "witch doctors."

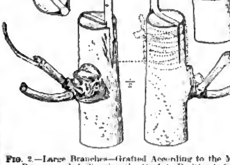

Fig. 2.—Large Branches—Grafted According to the Method Recommended, Showing the Graft in Position before it is Covered with Wax.

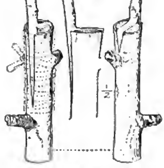

Fig. 3.—Small Branches Grafted, and Ready for Waxing.

craft—to the very earliest ages, probably even to paleolithic times. In various parts of Great Britain we find an analogue of lucky money in various stones known as lucky stones, mare stones, or hag stones, which are very highly valued. Most of these are small pebbles, with natural holes, indentations, or cups in them; they are used for driving away hags or witches, especially the nightmare, which is supposed to be caused by a witch sitting upon the stomach of the sufferer. An abstract from an old book of Queen Elizabeth's time is given in Notes and Queries,* containing "a fonde foolishe" charm for driving away the nightmare. "Take a Flynt Stone that hath a hole of hys owne kinde and hang it over hym." Three of these were exhibited by the Earl of Ducie at a meeting of the Anthropological Institute in 1887, one being remarkable from having two human teeth fixed in the natural hole of the stone. The teeth were probably used to increase the luck of the stone. This mare stone had been in one house seventy years; and similar stones seem to be in common use among the peasants and fisherfolk of the North of Scotland, being kept in the bed to ward off nightmare, hung in byres behind cows to insure safety in calving, or hung on stable doors to prevent horses from being hag ridden. The latter use is, I believe, still common in many parts of England, for I have frequently seen in Wiltshire stones, and sometimes a piece of cork with a hole in it, tied to the keys of the stable. Several of these holed stones used as amulets are described in the catalogue of the National Museum of the Society of Antiquaries of Scotland. Among these amulets we find four amber beads formerly used in Argyllshire as charms for the cure of blindness, and four spindle whorls called adder stones used as charms against diseases of cattle; also a flat oblong stone less than a quarter of an inch thick notched at the edges and pierced with two holes, formerly used as a charm for the cure of diseases in Islay, and two perforated pieces of sandstone found in cowbyres used as a protection for the cattle against witchcraft. In the foreign portion of the same collection is also to be seen a vertebra of a gazelle used in Palestine as a charm against evil spirits. I cite these instances to show that both natural and artificial holes were considered of the same value for the cure of disease and averting witchcraft, and that the same idea may be traced to Palestine.

The Red Indian medicine men, especially among the Cherokees, use beads to symbolize persons, and their shamans take beads and with them work spells for the benefit of their employer, and for the destruction of his enemies. Red is the lucky color and black the emblem of death. By some extraordinary manipulation these beads are made to move up and down the outstretched fingers of the shaman, and by their movements the success or failure of the spell is foretold. A certain formula or prayer is used to invoke success upon the client, the red bead being held between the finger and thumb of the right hand, while a black bead typifying the victim is held in the left. Curses are called down upon the latter, and then the shaman, stooping down, makes a hole in the ground with his finger, "drops into it the fatal black bead, and buries it out of sight with a stamp of the foot."† Purification by water is also associated with this ceremony, the shaman addressing a prayer to the stream near which the incantation takes place, while the client pours the water over his head, or dips in the stream seven times. In gathering medicinal plants, also, the Cherokee medicine man drops a red or white bead into the hole made in pulling up the root, in order, Mr. Mooney thinks, to compensate the earth for the plant torn from her bosom. In the Navajo myth of the creation of the sun, beads play an important part. Two women, known as the Turquoise woman and the White Shell woman, take white and blue beads, draw a circle round them with a crystal dipped in corn pollen, mark them with eyes and mouth, and produce a slight light from the white shell bead and a greater light from the turquoise. These are afterward multiplied by twelve at each of the cardinal points, and with a crystal a circle is drawn round the whole, and the crystal being held over the turquoise face, it lights up and becomes the sun. Here we get the magic circle which always plays such an important part in witchcraft, a survival of which seems still to cling to that symbolic circlet, the wedding ring, which, as we know, is used to cure a sty on the eyelid and other ailments, and to promote dreams.‡ Curative properties are not confined to the wedding ring, for, prior to the Reformation, cramp rings were solemnly blessed by kings of England, and distributed for the benefit of those afflicted with cramp or rheumatism; and silver rings are still worn for the same purpose, while earrings are commonly supposed to be a specific for weak eyes.

Curious instances of the healing properties still attributed to sacred stones in America are given by Mr. Bourke in his very interesting article, entitled "The Medicine Men of the Apache" in the Smithsonian Report of the Bureau of Ethnology (1888). He says that medicine men seem to be subject "to a gradual decadence of their abilities, which can only be rejuvenated by rubbing the back against a sacred stone projecting from the ground in the country of the Walapai, on the Atlantic and Pacific railroad." Another stone of the same kind was formerly used for the same purpose by the medicine men of the Pueblos of Laguna and Acoma, and he adds, "I am unable to say whether or not such recuperative properties were ever ascribed to the medicine stone at the Sioux agency near Standing Rock, South Dak., or to the great stone around which the medicine men of Tusayan marched in solemn procession in their snake dance; but I can say that in the face of the latter, each time that I saw it (at different dates between 1874 and 1881), there was a niche which was filled with votive offerings."

The St. Louis Age of Steel says: "The growth of the British mercantile marine, notwithstanding some recent periods of depression and the general revival of the shipbuilding industries in other countries, has by no means reached the decadence some suppose. In less than a decade the tables show an increase of 3,200,000 tons. A large percentage of this gain is due to the building of large steamships. In speaking of this matter a British contemporary says: 'We have 8,375 steamers of 9,900,000 tons. In fact, in ten years we have added over 6,500,000 tons of steamers, even after all allowance is made for sales, wrecks and waste generally, while the sailing tonnage is actually less than it was ten years ago by 462,000 tons. Antecedent to 1892 the average for some years was nearer 500,000 tons, although, in 1887, a minimum was reached with an addition of 46,600 tons.' That the shipbuilding industry will eventually be more evenly distributed among various nations is a foregone conclusion, and in this inevitable result Great Britain must be the greatest loser from competition."

* Vol. i, p. 34, Series VI.

† See "Sacred Formulas of the Cherokees, Smithsonian Report, 1885," Mooney, pp. 388, 394.

‡ "The healing power of the wedding ring was communicated to the finger upon which it was worn, which was supposed to cure any sore or wound stroked by it, all the other fingers being injurious, and the physicians of Greece and Rome used it to stir their medicines. GLACIERS.

Constructive Work of Glaciers: its Peculiarities—Moraines, Lateral, Medial, Ground and Terminal; Drumlins—Erratics and Perched Blocks.

Constructions by the Combined Work of Ice and Waters—Kames and Eskers—Overwash and Glacial Sand Plains.

THE following are excerpts from a lecture at Wagner Institute, Philadelphia, by Prof. W. B. Scott, of Princeton University.

Glaciers are found in Greenland, Alaska, the Antarctic Continent and elsewhere. A glacier does not move like a mass of ice, by sliding. Gravity is the moving force in both cases; but the ice of a glacier flows—it acts like a plastic body.

The different classifications of glaciers are based on size. We have, in the first place, the Alpine glaciers, because of their typical development in the Alps. They may be compared with small rivers and streams that occupy valleys at first carved out by water, and later occupied by these great streams of ice.

Among the Alps of southeastern Alaska the convergence of a number of streams has produced a glacier covering over 15 square miles of country. The movement of this great glacier is exceedingly sluggish, and in certain parts of it, it does not move at all; there you find it covered many feet deep with soil and rocks; and on parts of it is growing a luxuriant vegetation. It seems impossible to imagine this flora—you can't exactly call them forests, because they are trees and bushes, ferns and May apples, with laurels—growing most luxuriantly with a thousand feet of ice beneath them.

Then we have the great ice sheets comparable to seas of ice. As examples, we have the Greenland glaciers—the great ice cap, which covers thousands of square miles. The whole country from the coast mountains inward is covered a depth of several thousand feet with ice which is gradually flowing outward—eastward and westward to the Atlantic and Baffin's Bay. From this great inland sheet descend glaciers of the Alpine type, which fill the valleys, many of them coming down to the water; many of them ending a mile or so inland.

It is always easy to identify the work of a glacier. The same ice mass will be destructive in one place and reconstructive in another. It is a question of rapidity of flow; so we distinguish in the glacier the central zone and the peripheral zone. The central is where depth and rapidity of flow are at maximum; consequently, no material accumulation is possible at the center. Fifty feet a day is a tremendous movement for a glacier. This comparatively rapid flow carries away all the loose material, sweeping the rocks bare. As the glacier sweeps away this material, a great many stones of all sizes become frozen in the bottom and are dragged and pushed along. The rock bottom is scored; each stone, like a great chisel, cuts and grooves, and the parallel lines are kept perfectly true as long as the stones keep their relative positions.

Then again the glacier makes a curious kind of rock effect, "roche moutons," looking like a flock of sheep lying down. There is one steep side and one gentle side; and you always know that the movement of ice is in this direction—that the gentle side is upstream and the steep side is downstream; because, while you find this side polished by the sand and clay which has been pushed over it by the moving ice, this downstream side, never having been subjected to pressure, may still retain its primeval roughness. Besides the scoring and polishing of the rocks produced by the glacier, it markedly changes the shape of the valleys; an Alpine or valley glacier always changes the character of the valley in which it occurs, such valleys originating through the action of water. The typical form of a stream valley is a V shape, much narrower at the bottom than at the top. The ice filling the valley commences to tear out the sides, and instead of having a V shape, you will get a U shape with a flat bottom. When the glacier has retreated, the valley has a peculiar shape water never gives.

Then a true fjord is unmistakable evidence of glacial action. A fjord is a valley of terrestrial origin which the sea has invaded; and the picturesque beauty of the coasts of Norway, over which travelers are wild, is due to this fact. You have these extraordinarily precipitous-sided rock valleys into which the sea penetrates for many miles, and each one of these fjords is a valley first cut out by water; secondly, modeled by the moving ice into the peculiar glacial forms; and thirdly, submerged so that the sea has come over it. Some of these fjords have two or three thousand feet of water in them. Here, evidently, the fjord has been greatly deepened by the great glaciers which at one time flowed out through them.

The rocks are not solid sheets of material, they are broken up by innumerable joints into blocks; and so, wherever glacial ice would find a block, it would shove it along; and these separate blocks would be worked out one after another and the valley shaped and modeled in this peculiar fashion.

Dealing with the constructive work of glaciers, the North American continent, down to the latitude of 40°, is modified in its topography by the great sheets of ice. In the far north, where the glaciers accumulated and were thickest and swiftest, we have the central zone, with hardly any soil left, as in much of northern Canada, where there is nothing scarcely but naked rock; but from southern Canada to latitude 40 we have a million square miles of country covered to an enormous depth with drift, which is the generic and general term for the material deposited by the great ice sheets; because these were not single valley glaciers, but sheets comparable to those of Greenland and the Antarctic. This drift is of many kinds. The drift's relation to the ice that brought it, whether carried on top of the glacier, in the middle, or shoved along underneath—all these determine the characteristic topographical features which the drift assumes.

So we have the glacial moraines. The scientific study of glaciers began in French Switzerland; and so, just as nearly all our terms regarding volcanoes, so most of our terms regarding glaciers are French. Moraine means the line of rubbish the glacier carries. We have in a valley glacier numbers of moraines—among them, lateral moraines, carried along the side. These are rock masses tumbled down upon the glacier from the cliffs; and if there are no overhanging cliffs—as in Greenland—then you will get no lateral moraine; because there the cliffs are buried out of sight in the enormously thick field of ice. It looks very strange when you first go to Switzerland to see a stream of ice a mile wide, with a great regular line of stones—from a thousand tons down to grains of sand—piled up in long lines in the middle of the glacier, half a mile out from the sides; until you find that the immense moraine is produced by two branch glaciers.

The material underneath the glacier (as long as the glacier moves with some speed) is pushed with it; but when thinned down by melting and you get out into the peripheral zone (with weight and speed reduced) all this stuff is left behind and the glacier rides on over it. This is the ground moraine.

The lower end of a glacier—whether a valley glacier or a great ice sheet—is determined by the point where melting and flow just balance; consequently, when the ice reaches this point, down goes everything that the ice has been carrying; and the great difference between glacial deposits and water deposits is that the ice deposits are entirely unstratified. A glacier, no matter how sluggish its movement, will carry a block of stone that weighs a thousand tons with just as much ease as it does the finest particle of dust; so when the glacier is melted, down goes everything in a promiscuous heap; and you will find these vast bowlders, sand and gravel, earth and soil, all mixed together without the slightest arrangement. That is the terminal moraine.

Besides these, we also get lateral moraines, because, when the glacier is shrinking, it does so not only from the end upward, but from the side, just as a river when its supply of water is diminishing, and it falls, retreats laterally into its channel; so that a glacier that has been filling the valley up to a certain level, when the climate becomes warmer or when the snowfall is diminished, does not cut down so far as it used to, but shrinks laterally, and the lateral moraine is left at one side stranded. The blocks of stone carried on the edges will be left behind. There is a great block of stone in eastern Long Island about half the size of this building; another great bowlder on the edge of a cañon in the plains measuring twenty-four feet in diameter, with estimated weight of twenty thousand tons. Sometimes these great bowlders are let down so gently by the shrinking ice that they make rocking stones, and you may move backward and forward with your hands a great bowlder that weighs a thousand tons or more. There are plenty of such instances.

Besides these general masses of moraine material, there are constructions around, in and underneath the sheet, especially at its edges, produced by the combined work of water and ice. Every stream of ice has water flowing under it. Even in Greenland there are subglacial streams; in the fiercest frosts of an Arctic winter the stream of water issues from underneath the ice. Ice is an excellent non-conductor, and protects the subglacial stream from the action of the intensely cold atmosphere.

Some of these sub-glacial streams are very swift. Glaciers always flow down considerable inclines, where water rushes with torrential violence. They flow through in channels they make by melting their way. In the glaciers great streams flow beneath the lake of ice from the north, pass under its whole length and come out at the south. Many of these streams are under tremendous head, as the engineers would call it, and so loaded with gravel and sand that when they come out to the surface they rise up as huge fountains, sometimes twenty feet high, and, of course, their velocity is immediately checked and they choke themselves with sand and gravel, forcing themselves to melt out new channels.

When the ice has retreated by melting, these subglacial stream channels would be left standing as long, winding ridges of gravel and sand. These have been actually observed in process of formation in Alaska in a glacier which is retreating very fast. In the last hundred years it has gone back a mile or two. It used to be in the sea, and now it is not within a mile of the sea, and instead of the ice-covered area, we have a delta area, where innumerable streams are coming out from the ice and depositing these materials.

In regions like Central New York and New England and Central Illinois we find a great many eskers where these ice streams originally were. These eskers come together exactly like streams, and evidently are old sub-glacial stream channels choked up by the action of the ice. These eskers (or, as they are called in Scandinavia, asar) are a very conspicuous topographical feature.

Another topographical feature produced by the glaciers is kames—short hillocks or ridges of drift gravel, sand and the like formed on the edge of the ice front. These fronts are irregular at the base. A stream of water coming out from under the ice at this point under great pressure spouts up a fountain, throws out sand and gravel and fills up an area with a mass of partially stratified drift, which, when the ice melts and goes back, will be left standing as an isolated hillock or kame.

Drumlins.—Thousands have been found in the glaciated regions of this country. They also have been produced near the edge of the ice front; and their manner of formation is a very complicated one. Below the front of the ice where the escaping waters come out we have the material that these glacial streams were carrying, spread out in sheets. If the subglacial stream happened to find a valley ready to receive it, it flowed down the valley, leaving the coarsest material up at the top and finer and finer as it got down. These

streams of glacial material thus left in the valleys are called valley trains, and are due to the material prepared by the glacier and carried off by the swiftly moving water. If these streams were carried onto a plain, they would deposit most of the material which they would carry. Then we get a glacial sand plain, produced by the waters escaping from under the edge of the ice front.

So we see glacial topography, whether of destruction or construction, is pre-eminently characteristic. It is a mountain flowing torrent with no crags in it. Wherever the ice has overflowed the rocks it has covered them and polished them. Two or three hundred feet is perhaps the limit of height. The winding drumlins all formed in this one kind of way and no other.

THE KLONDIKE GOLD FIELDS.

THERE is always something particularly exciting about the discovery of a new El Dorado; so that when, on July 14, the stories of the fabulous richness of the new Klondike, near the upper Yukon River, just over the border of Alaska, in British America, were confirmed by the arrival of forty miners with gold amounting to over $500,000, an exodus of miners began at once.

The Klondike gold fields are not in Alaskan territory, as was originally supposed; they are in the British provinces in what is known as the "Northwest Territories." The Klondike River, which has been on the map for about twenty years, but not under that name, is a branch of the Yukon River. The gold fields are most easily reached from Chilkoot Inlet. Steamers run there from Sitka and from Seattle and Tacoma. The distance from the head of Chilkoot Inlet to Klondike is about 500 miles. To reach there it is necessary to cross the coast mountains and the chain of lakes and short streams which form the head waters of the Yukon River. It is along these streams the gold is found. The country is a rolling one and is covered with grass and subject to great extremes of heat; so that the mortality among the miners will probably be very high. There is a short, hot summer of four months, with practically no spring or autumn. The ice does not break up until about the last of May, when navigation commences on the Yukon River. By the latter part of September it gets very cool. Winter comes about the first of October, and it is very cold and dry, with little snow and rain. The thermometer sometimes falls 68° below zero in January and February, and sharp winds are prevalent. The dress of the natives and the miners is mostly of fur in winter. Dr. W. H. Dall, one of the curators of the National Museum, who has spent much time in Alaska, states that gold was first discovered there in 1866 and has been taken out in profitable quantities for fifteen years or more, but nothing like the boom of the last few weeks has ever visited the gold fields. The gold bearing belt of northwestern America contains all the gold fields extending into British Columbia and what is known as the Northwest Territories and Alaska. The Yukon really runs along that belt for from 500 to 600 miles, the bed of the river being in the valley. Gold is not found in paying quantities in the main river, but in the small tributary streams which cut through the mountains. In most cases the gold lies at the bottom of thick gravel deposits.

There is another method of reaching the gold fields. This is by the Yukon River, though it is much longer, being 1,500 miles. Flat bottom steamers run from St. Michael's up the Yukon. The return trip is usually made by these steamers. As the gold fields are situated in a country where there is practically nothing upon which to subsist, it is necessary for the miners to carry enough supplies to last a year. Even last winter, when the number of miners was very limited, the supply of food was inadequate, and rations had to be doled out. The several thousand miners who are now on their way to the Klondike, many with inadequate provisions, bid fair to cause one of the greatest catastrophes in mining history. Canada is quite aroused over the discovery of gold in the northwest provinces. Custom house officers and mounted police are being rapidly dispatched toward the frontier.

The miners who have returned to San Francisco bring startling tales of the marvelous finds of gold which discount the stories of 1849. The excitement on the river is indescribable. One man has worked forty square feet of his claim and obtained $40,000 in gold dust. The estimated extent of the district is thirteen square miles, and it is thought that the claims will average $300,000 and some are valued as high as $1,000,000. Labor costs $15 a day and upward. Some of the miners who have returned to San Francisco brought from $80,000 to $150,000 as the result of their few months' work. The method of mining is to remove the surface moss, which is eighteen inches thick, and then build a fire which burns all night. In the morning the gravel is shaved down about two feet; this is shoveled out and another fire is built. In this slow and laborious way the ground is removed to bed rock. This work can be carried on all winter, and there is so much labor connected with it that there is little wonder that the price of employment is so high. All provisions are scarce and dear. Last winter eggs sold at four dollars a dozen and flour at a dollar a pound. It is a curious fact that the Klondike gold is inferior to that obtained in California, or even in other localities near the Yukon. It averages only $15 per ounce, while gold from the regular districts in California averages from $18 to $19 per ounce. As the yield will amount to millions of ounces per annum, the difference is a vast one.

The steamer Excelsior on her next trip from St. Michael's, which will be about September 5, will bring between $5,000,000 and $6,000,000 in gold dust. The transportation companies are taxed to their utmost, and more than five thousand miners are expected to reach Klondike next fall, and it is said that fully twenty thousand would attempt to go there if they were assured of transportation.

The story told by the returned miners is that rich discoveries have also been made in Alaska, just over the border. In fact, it now appears that the rich promise of the whole region has not been a secret among the northern gold hunters during the last few months, but the fame of the Klondike region has become such that every one wished to hurry to that region. It is expected that every mail from Alaska will bring the news of other gold fields which are comparable to those of the Klondike.

THE

Scientific American Supplement.

PUBLISHED WEEKLY.

Terms of Subscription, $5 a Year.

Sent by mail, postage prepaid, to subscribers in any part of the United States or Canada. Six dollars a year, sent, prepaid, to any foreign country.

All the back numbers of THE SUPPLEMENT, from the commencement, January 1, 1876, can be had. Price, 10 cents each.

All the back volumes of THE SUPPLEMENT can likewise be supplied. Two volumes are issued yearly. Price of each volume, $2.50 stitched in paper, or $3.50 bound in stiff covers.

COMBINED RATES.—One copy of SCIENTIFIC AMERICAN and one copy of SCIENTIFIC AMERICAN SUPPLEMENT, one year, postpaid, $7.00.

A liberal discount to booksellers, news agents, and canvassers.

THE CANET RAPID FIRE ARTILLERY.

I. NAVAL GUNS.—M. Canet, now superintendent of the Creusot artillery, after persevering experiments and successive improvements, succeeded a few years ago in constructing a complete naval artillery material, the superiority of which over all others has been demonstrated by experience.

Such material is organized upon the following principles: The bore of the gun is of great length, ranging from 45 to 50 and even 80 calibers. The contours give ample security against flexions or bursting of the chase, a chamber of large size permits of using quite a strong charge, and, by reason of the length of the bore, the initial velocity may reach 800 and even 900 meters per second.

The breech piece is a cylindrical screw, the simple and rapid maneuvering of which is done by a single movement of a lever. It is provided with safety apparatus to prevent a premature discharge and the unscrewing of the breech piece. The extraction of the shells is done progressively by means of a claw, which grasps their base.

The carriage, which is simple and strong, is provided with a hydraulic brake of constant pressure, with a recuperator that permits of obtaining a return to battery sufficiently rapid and without any shock. It is balanced around axes of rotation in such a way as to reduce the stresses of pointing. It permits the piece to recoil according to its axis, whatever be the angle of fire. This material, which is perfectly elaborated in all its parts, and which embraces in its arrangements of detail the latest improvements, comprises guns of 10, 12 and 15 centimeters.

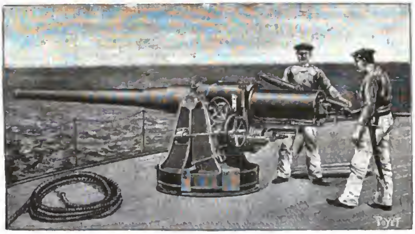

FIG. 1.—CANET 10 CM. RAPID FIRE NAVAL GUN—MODEL OF 1888 (48 CALIBERS.)

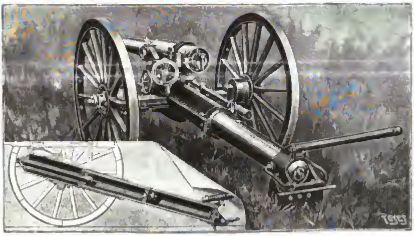

FIG. 2.—CANET 75 MM. RAPID FIRE FIELD GUN.
Piece in firing position. Section of carriage with elastic mounting.

The gun is wholly of steel, and is formed of a tube that extends throughout the length of the piece, of a jacket which rests in the rear against a shoulder piece, and of a conical ring that prolongs the jacket in front. The chamber, in the form of a truncated cone, is united with the cylindrical part through a reinforcing sleeve, and the grooves preserve a constant width up to the muzzle. Their inclination varies from 0 to 6°.

The breech mechanism permits of effecting the three motions of rotation, withdrawal and turning back the breech block at the side through a maneuvering of the screw by a simple movement of the lever in a horizontal plane. The breech is opened through a motion of the maneuvering lever from right to left. At the beginning of the motion, the revolution of the lever around the pivot unscrews the block. The teeth of a bevel gear placed in the posterior cavity are carried along by a pinion with vertical axis fixed to the bracket of the breech block. At the same time, a wheel traverses the circular part of the slide, and a cam carried by the pivot abuts against the posterior edge of the block seat. If the action upon the lever be continued, the pivot as well as the breech screw will be pulled backward. At the end of the motion, the entire system, having become interdependent, will pivot around the axis, and the breech will be open. The closing is likewise effected through a single motion, but in an inverse direction. The firing may be done either mechanically by means of a percussion primer or by electricity.

The carriage has a central pivot and is of limited recoil, with an automatic device to bring it into firing position again. It comprises (1) a sleeve which surrounds a portion of the reinforce of the gun; (2) an oscillating frame upon which the sleeve rests; (3) the carriage, properly so called, of cast steel, formed of two cheeks that support the trunnions of the frame; and (4) of a cast steel base bolted to the deck of the ship and the center of which carries a column of Belleville springs, which are compressed during the firing. The hydraulic brake that limits the recoil and brings the piece back to the firing position is of what is called the "central counter rod system." It consists of a cylinder, of a piston whose rod is fixed in the head, of a valve resting upon the back of the piston through the pressure of springs, and of a rod that enters a central orifice formed in the piston.

The recuperator consists of a piston surrounding the piston rod and of a cross piece carrying two columns of springs.

At the moment of firing, the gun recoils in the sleeve, carrying with it the head and, consequently, the piston. The liquid contained in the brake cylinder is then forced to the front of the piston and passes through the annular orifice between the edges of the central aperture in the piston and rod, whose variable profile permits of regulating at each instant the section of such annular orifice and, consequently, the pressure developed. It afterward passes through orifices formed in the piston and lifts the valve. The recoil of the springs brings the gun back into firing position in forcing the liquid to the end of the piston. The projectiles are of two kinds—an ordinary cast iron shell and a bursting shell of chrome steel. Their brass cartridges, closed at the base by a screw plug, contain the charge of powder.

These guns require but four or five men to maneuver them. They permit of doing the firing with a rapidity that may reach from ten to twelve shots a minute, when no pointing is done, and five or six shots a minute when pointing is done at every shot. The 12 cm gun throws a 25 kg. projectile with an initial ve-

locity of 780 meters per second, and the 15 cm. gun throws a 66 kg. one with an initial velocity of 750 meters per second.

II. Field Guns.—The construction of a rapid fire field gun constitutes a problem that is far more complicated than that which concerns a naval, place or siege piece. Nevertheless, after some comparative studies and experiments in firing carried on almost uninterruptedly since 1880, M. Canet has succeeded in constructing a rapid fire field material, all the elements of which have been perfectly combined, and which affords a remarkable solution of the problem from the standpoint of power, mobility and rapidity of firing.

The principles upon which the construction of this material is based are as follows:

The gun, which consists of a tube, reinforced by a long sleeve that receives the breech of a fixing ring and of a ring carrying the trunnions, presents every guarantee of resistance in the longitudinal as well as in the transverse direction.

Three systems of screw closing permit of obtaining rapidity in the maneuvering of the breech block. One of these, which has a cylindrical screw, and the simplified parts of which are capable of being manipulated almost instantaneously without any tool, opens and closes the breech by two successive motions of the lever without releasing the maneuvering handle. The second, which has a conical screw, is maneuvered very rapidly, by a single motion of a lever in one plane. The third, with concentric threads, and entirely new, is maneuvered very simply by a single motion of a lever. The three systems are provided with automatic extractors, that assure the ejection of the brass cartridge shells. All three are equally well adapted for the use of percussion or electric primers. The carriage constitutes a genuine innovation. It is distinguished from the rigid systems in that it almost completely suppresses the lifting and reduces the recoil to a minimum, its length being variable, the fixed part being reduced to the stock, and almost the entire weight participating in the recoil of the piece. The projectiles are separated from the cartridges during carriage, and are inserted rapidly at the moment of firing.

The ammunition is of an entirely new type. The sole projectile is a shrapnel formed of a steel shell containing a series of cast iron disks in which are embedded balls of hardened lead. A central tube permits the fuse to communicate with the charge behind. Around this tube is rammed down an inexplosive material which, at the moment of the bursting, gives out a thick cloud of smoke (visible at a great distance), and which is capable of setting fire to combustible substances. Steel shells of large capacity, with a solid point and with a slow fuse designed to retard the bursting, are reserved for the attack of fortified works. The cartridges are stamped in a single piece out of brass or aluminum. At the base they carry either a percussion or an electric primer.

The Canet guns may be fired with smokeless powder having either nitroglycerine or guncotton as a base. The initial velocity reaches 500 meters in short guns and 600 in long ones of the type of 75 mm. The weights of the guns are respectively 250 and 330 kg.; those of the carriages are 500 and 630 kg.; and those of the shrapnels are 4·6 and 5·2 kg. The maximum range is 5,000 and 6,800 meters.

The rapidity of the firing, in training every time, is ten shots a minute. Such are the principal elements of this material. We cannot enter here into a description of all the details, which have been carefully studied in view of the object to be attained. The material has been submitted to prolonged rolling tests at all speeds over paved roads, and to numerous experiments in firing, at the Hoc proving grounds, and has in all cases behaved admirably.—La Nature.

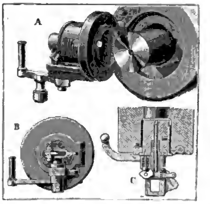

Fig. 4.—BREECH MECHANISM OF THE 10 CM. GUN.

A, the breech open; B, front view; C, horizontal section.

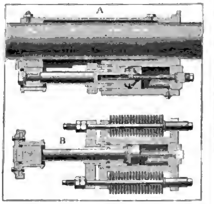

Fig. 5.—HORIZONTAL BRAKE WITH CENTRAL COUNTER ROD AND ITS RECUPERATOR.

A, longitudinal section; B, vertical section.

The rapid fire field artillery of the Canet system, model of 1896, comprises the following guns:

	Heavy material.	Light material.
75 mm. caliber..	Gun of 30 calibers.	Gun of 24 calibers.
70 " ..	" 30 "	" 24 "
65 " ..	" 35 "	" 30 "

The carriage, with elastic tubular mounting, of these guns consists of two principal elements. One of these, which is stationary during the firing, consists of the trail plate and the stock; and the other, which is movable, comprises the part of the frame that slides upon the tubular mounting during the recoil and the return to the firing position, the carriage properly so called, the axle and the wheels.

The stock is formed of a forged steel tube containing a hydropneumatic brake and which enters the tubular mounting after the manner of a telescopic tube. At the end it carries, screwed on firmly by a ring, a trail plate and its accessories.

The tubular mounting carries a circular plate cast in a piece with it upon which rests the gun frame. The latter has two cheeks which are strongly cross braced and connected beneath by a circular plate that corresponds to that of the tubular mounting. The surfaces in contact are trued up with great precision, so as to permit of pointing without any effort.

A maneuvering hand wheel, through an endless screw, moves the toothed sector fixed to the mounting and permits of giving the gun the motions for training in horizontal direction. A second hand wheel, a little to the rear and at the side, controls the mechanism for training in a vertical direction through the intermedium of a pointing box and a vertical screw. The axle, which is of forged iron, and curved at the center, is cranked at its extremities in order to permit of the use of wheels of wide diameter.

The hydropneumatic brake in the interior of the steel tube is of a very simple and strong type that assures the regularity of its operation and requires no looking after.

At the first shot the trail plate enters the earth. An insignificant recoil that does not exceed 50 millimeters, and that varies, moreover, according to the hardness of the ground, occurs at the first shot, and then the trail plate and stock are rendered immovable. At every shot the entire movable part freely recoils, and the tubular mounting slides upon the stock and actuates the brake without the wheels leaving the ground. Then, the energy having been absorbed, the return to a firing position takes place and the carriage resumes the position that it previously occupied.

OUR SEWING MACHINES.

MORE THAN 500,000 MADE BY US ANNUALLY.

America is the sewing machine center of the world, and New York is the center of the sewing machine industry of America. In this city nearly all the great factories producing these machines are directed and controlled, and fully 90 per cent. of the sewing machine trade of the world is managed and handled here. The production amounts to more than 500,000 machines annually, and nearly 100,000 persons in one way or another make their living out of sewing machines, either as factory operatives, agents, clerks, canvassers, collectors, or in some other capacity connected with the making and marketing of machines. One of the largest of the companies has an agency of its own in nearly every city, town and village in the United States, besides being represented by its own agents in every city of importance throughout the world.

The American sewing machine, like the American watch and the American reaper and mower, is the standard of excellence for the civilized world, and the export trade in sewing machines penetrates to the uttermost ends of the earth. New York is the great sewing machine center of the world, because, in addition to being the headquarters of the industry in the United States, it is the home of a company which operates several factories in Europe, among them one in Scotland, where 6,000 persons are employed. The machines manufactured abroad under American patents are not included in the statistics of the export trade, though their manufacture in Europe cuts off our export trade to that extent. Everywhere throughout Christendom the American sewing machine holds the market against all competitors. It is not a question of price, but of merit, quality and reputation. The only country that is making any headway in the struggle for the sewing machine trade is Germany. There they have gone into it seriously, and are turning out machines that show a great improvement over their product of a few years ago.

"Germany is hot after us for the world's market," said a sewing machine exporter to the Sun reporter, "and she is making such excellent machines that the competition threatens to become important to us. German manufacturers have some facilities which Americans do not have for obtaining advances from their banks upon goods consigned to foreign markets, and they can give their commission men six to nine months' credit on all machines handled by them, and the same credit is extended to the buyers wherever they may be located. Here in New York the sewing machines for export are sold for cash, and no credit is extended to the buyer. We are, therefore, at a disadvantage in this respect, and Germany is increasing her foreign trade at our expense. She is making a strong bid for the South American trade and is meeting with considerable success. German efforts to sell sewing machines to France have not fared so well. No matter how cheap the price or how long the credit, the Frenchmen will not buy of their enemy, but keep on taking American machines."

The money value of sewing machine exports for the year 1895, and for the thirty years ending with 1895, was as follows:

	1895.	Total for 30 years.
Austria-Hungary	$12,160	$81,709
Belgium	35,200	790,845
France	98,506	2,645,045
Germany	472,365	15,417,688
Holland	22,018	408,800
Italy	6,750	204,821
Portugal	77	15,088
Russia	....	130,580
Spain	1,814	78,977
Sweden and Norway	8,019	101,658
Switzerland	100	8,729
Turkey	137	23,085
Great Britain	645,847	22,952,623
British North America	111,388	2,122,028
British Australasia	224,875	4,425,036
British West Indies	13,628	241,136
Hayti	4,006	123,428
San Domingo	1,817	70,908
Cuba	16,114	2,241,264
Dutch West Indies	1,069	68,841
Denmark	1,958	31,161
French West Indies	1,849	32,209
Porto Rico	2,290	212,768
Mexico	132,841	4,018,192
Central America	64,970	903,967
British Guiana	8,189	21,192
Dutch Guiana	324	1,044
French Guiana	1,014	5,911
Colombia	30,924	2,620,533
Bolivia	830	3,329
Ecuador	11,402	147,249
Brazil	140,054	2,318,240
Argentina	53,504	1,485,700
Uruguay	13,817	820,784
Venezuela	46,248	970,615
Peru	8,600	488,712
Chile	21,894	500,122
Africa	7,823	102,081
China	3,001	90,817
Japan	3,465	91,622
Hawaii	9,968	269,040
East Indies	1,303	48,028
All other countries	9,277	276,378
Totals	$2,260,189	$67,245,243

For 1896 the total exports were $3,051,108, a gain of $791,089 over the preceding year. There was an increase in the sales to the United Kingdom, British Australasia, Africa, Germany, France and some of the South American countries, and a slight falling in the number of sewing machines sold to Canada. The figures relating to France include only the sewing machine heads, as under the high retaliatory duty enforced in France against American products it is not found profitable to export the iron stands and wooden cabinets. For February, 1897, the total value of machines exported was $244,786. Cuba, which in 1895 took $16,114 worth of sewing machines, in 1896 fell off to $3,061, and this was mostly for attachments, needles, etc. The unhappy Queen of the Antilles, wrapped in the horrors of war, has had little use for anything but food, firearms and ammunition.

The annual average of sewing machine exports during the past ten years has been over $2,500,000 in value. This does not include the 200,000 machines made annually in the Scotch factory already referred to. The same company operates a factory with 4,000 employes at Elizabethport, N. J., and a curious confirmation of the vaunted supremacy of American over foreign labor is found in the fact that the 4,000 Yankees in New Jersey turn out as many machines as do the 6,000 Scotchmen at Kilbowie. Of the total of 13,500,000 machines made by this company from 1853 to the end of 1896, nearly 6,000,000 have been made in factories located abroad, but directly controlled and managed by the New York company. The average value of the exports of sewing machines from the United States indicates that about 150,000 machines are exported annually, and the total number of American machines sold annually in foreign countries, including those made abroad, is equal to the sales in the United States by all the American companies.

"The export trade has been the salvation of the sewing machine industry in the United States," said the president of one of the leading companies. "During the financial depression of the last four years there has been a marked decrease in domestic sales, and sharp competition has affected prices unfavorably. There has been cutting of prices in all directions, and some of the biggest companies have taken a hand in it. The sale of sewing machines at cut prices by the large department stores has had a demoralizing effect, and it is not to be denied that some very excellent machines are being marketed in this way at low figures. So far the big standard companies have kept their machines out of the department stores, but they would have found it difficult to keep their factories running on full time if it had not been for the export demand."

There have been great fortunes made and great fortunes missed in the sewing machine industry. Elias Howe realized over $1,600,000 in royalties and license fees for his inventions and improvements, and Isaac M. Singer lived to see the business of which he was the founder develop into colossal proportions from the investment of $40 and no end of patience, perseverance and skill, from which the sewing machine industry started a little less than half a century ago. Other men have grown rich in the business, and from its development and operation vast additions have been made to the wealth and prosperity of the country. Howe and Singer seem to have been the only ones among the earliest inventors who reaped substantial rewards. The others lacked the faith and persistence to perfect and utilize their ideas, and so missed their great chances in life.

As long ago as 1851 New York became the sewing machine center of the universe, and has steadily maintained that position to the present time. Factories were located in other cities, but their headquarters were in New York, and the commercial end of the business was always transacted here. At an early date

Orlando B. Potter became identified with the sewing machine industry, but he retired in 1875, several years before his death. In the litigation growing out of the infringement of Howe's patents, Messrs. Jordan & Clark, a New York law firm, were employed as counsel by I. M. Singer & Company in 1851. At that time Ambrose L. Jordan was attorney-general of New York State, and the sewing machine suits were looked after by his partner, Edward Clark. The clients were too poor to pay the large costs and counsel fees which accrued in the course of the litigation, and in payment for his services and for money advanced Mr. Clark accepted an interest in the firm, and in 1852 took charge of the legal and financial branch of the business. It was he who, in 1856, instituted the system of selling sewing machines on the installment plan. This, it is believed, was the inception of a system that has now become universal and all-embracing in its scope. From 1876 to 1882, the date of his death, Mr. Clark served as president of the wealthy and prosperous corporation which he had served as attorney in its impecunious days.

It is now twenty years since the expiration of the last important patent on a fundamental principle of the sewing machine; but the inventive genius of the age has not been idle all this time, and patents covering devices of greater or less utility have been granted in large numbers. From February 21, 1842, to September 10, 1895, there were issued by the United States 7,439 patents for sewing machines and accessories. Many of these patents cover several minor features of the sewing machine. So that the aggregate of patented inventions is much larger than 7,439. Among the patents issued during the fifty-four years ending with 1895 were the following:

Sewing machines making the chain stitch	433
Sewing machines making the lock stitch	661
Sewing machines for stitching leather....	431
Machines for sewing on buttons...	88
Machines for making buttonholes	448
Feeding devices	316
Miscellaneous parts of sewing machines..	2,930
Attachments, rufflers, hemmers, corders, etc....	1,524
Cabinet cases and tables	473
Motors, foot, hand, steam, electric.......	170

The earlier machines had no driving power except the common hand crank. This involved the use of the right hand, and only the left hand could be used for managing and guiding the material to be sewed. Isaac Singer conceived the idea of using a treadle similar to that employed on the old spinning wheel, and also discovered that with the addition of a balance wheel on the upper shaft for increasing the momentum he could run his machine by foot power. Soon after came the iron stand with the rocking treadle for both feet. Mr. Singer missed a great chance here. He did not realize the supreme value of these discoveries, and so neglected to take out patents. Two years later, when his devices had become public property, he saw the lost opportunity. One of the latest devices for driving a sewing machine is a revolving treadle with the bicycle movement, but none of the new wrinkles have proved so satisfactory as the old fashioned rocking treadle.

The proportion of hand to foot power sewing machines used in Europe and in Asiatic countries is far greater than in the United States. The operation of a sewing machine by hand power in this country is exceptional and is usually confined to those in some manner crippled or physically unable to apply foot power. In Europe and Asia much of the sewing machine work is done by peripatetic operatives who travel from house to house and carry along their own machines, and as they find the iron stands and wooden cabinets an impediment they prefer the hand power machine that can be rested on a table, bench or box.

In no branch of manufactures has a greater revolution been wrought by the sewing machine than in boots and shoes. By its aid the quality, style, and value of footwear have been greatly enhanced, while prices have steadily declined, until there is no nation on earth to-day whose people are so well and so cheaply shod as are the people of the United States. Changes in shoemaking methods and processes have been most radical. Formerly the fitting of the uppers was accomplished by sending them out in small quantities to be sewed and stitched by hand in the homes of the operatives. When sewing machines were introduced the scattered home industry was concentrated in factories, and steam power was employed for driving the machines. In 1861 the first machine for sewing on soles was put into successful operation, and a royalty of two cents on each pair of shoes was exacted by the owners of the patent. They must have had a liberal income from this source, as in one day of ten hours 900 pairs of shoes could be sewed on one machine, and by the aid of machines 350,000,000 pairs of shoes had been made up to the year 1877 in the United States, and probably an equal or greater number in Europe. The machine now in general use does its work in a manner closely resembling hand sewing, and is sold on a royalty plan based on the rate of production. This machine is considered one of the marvels of an age of mechanism. It is said that after examining the operation of the sewing and welting machine of to-day Thomas A. Edison declared it to rank equal with the Blanchard lathe in ingenuity and importance. Certain it is that a shoe which can be bought at retail for $3 is in all respects equal and in many respects superior to the $5 shoe of fifteen or twenty years ago. Another effect of machinery has been to greatly increase the finish and beauty of ready made shoes.

Button hole machines have also had a large sale on the royalty plan, and have been very remunerative to the owners of the patents.

During the early years of the sewing machine, the custom tailors showed great prejudice against its use, but this prejudice has wholly disappeared, and the machine is now in general use for making the finest garments. The enormous increase during the past ten years in the factory production of clothing has been coincident with and largely the result of the invention of special appliances and attachments adapting the sewing machine to factory operations in the performance of all stitching processes, including button hole and eylet making, attaching buttons, staying seams, etc. From 1880 to 1890 there was an increase from 6,166 to 18,658 in the number of establishments in the United States devoted to the manufacture of men's clothing, and during the same decade the number of establishments devoted to women's clothing increased from 562 to 20,811. The last mentioned figure includes custom dressmaking establishments having a product of over $500 in value, whereas the smaller figure for 1880 does not include the custom dressmaking establishments.

The concentration of the manufacture of clothing into factory operation, alone made possible by the sewing machine, has effected some important economies in the marketing of the cloths, especially the cheaper fabrics, such as jeans, denims, shirtings, etc. These goods are now sent directly from the mills to the factories where overalls, shirts and other articles of clothing are made, and no longer pass through the hands of the selling agent, the commission man, the wholesaler, the jobber and the retailer, each of whom formerly enjoyed his slice of profit in the handling. The extent to which wearing apparel of all kinds has been cheapened in consequence of the sewing machine could be expressed only by figures running far into hundreds of millions.

It is also an interesting fact that while the large manufacturing industries dependent upon the sewing machine much more than doubled their output from 1880 to 1890, the population of the country only increased one-quarter. It therefore follows that the quantity of sewing done in the home has been greatly reduced and the cost to the consumer of sewing machine products greatly lessened. A man well informed in the sewing machine trade on a large scale said to the Sun reporter:

"It is in the use of sewing machines in factories that the greatest revolution has been effected. You will doubtless be surprised when I tell you that the sewing machine in the home, taking the rich, the well to do, the families of the well paid wage earners, and the poorest of the poor altogether, does not average over twenty hours in the whole year. It is no longer used at home for making garments; the factories produce these at a price so little in excess of the cost of the cloth that it is no object for the housewife, be her circumstances ever so straitened, to employ her time in making clothes for the members of her family. Women at home use their sewing machines only for an occasional bit of stitching, and while none of them would consent to be without a machine, the use of it is surprisingly small. This is one of the greatest boons conferred upon women by the sewing machine, for it has left them leisure for other employments or enjoyments."

In the census reports relating to the principal manufacturing industries that use the sewing machine largely, the figures show that the total value of their products in 1890 had increased about 75 per cent. as compared with the value of their products in 1880. These industries employed 661,000 hands in 1890; they had about $437,000,000 invested in machinery, tools, and implements of all kinds, and the total value of their product was $1,161,196,850. The manufactures in which sewing machines are essential are awnings, tents, sails, bags, bookbinding, boots and shoes, clothing for men and women, corsets, flags, banners, men's furnishing goods, gloves, mittens, hats, caps, pocketbooks, rubber and elastic goods, shirts, saddlery and harness, and horse clothing.

The reports of the sales of sewing machines during 1873-76, the period of the "sewing machine combination," which was entered into by the leading manufacturers twenty-four years ago, show a total of 2,303,041 the average a year being about 576,000. Since 1876 there has been no available information other than that indicated in the census reports. These figures indicate that the average number of machines made annually during the last twenty years in the United States has been from 500,000 to 800,000, and that the average first cost per machine has been about $20.

A comparison of the census reports of 1880 and 1890 shows a decrease of 50 per cent. in the number of establishments engaged in the manufacture of sewing machines, but it also shows that there has been no perceptible decrease in the number of persons employed, and that their average wages had increased about 10 per cent. during the decade. In 1880 the average wages were $485, and in 1890, $567 per annum. The reports from fifty six establishments in 1890 showed the employment of 9,121 operatives, whose wages amounted to $5,170,555. The market value of their product was $12,823,117, so that the item of labor constituted about 40 per cent. of the total value. The relative figures have not changed materially during the last seven years. It is estimated that at present about 10,000 operatives are employed in the sewing machine factories of the United States and that the number of machines produced is but little in excess of 900,000. The average rate of wages is about the same as in 1890.

Nearly all of the large sewing machine factories of the United States are located within a few hours' ride of New York City, and this city is in effect the point of departure of the great bulk of sewing machine shipments. Scarcely a steamship clears from this port for any part of the world but carries one or more American sewing machines, while large numbers destined for China, Japan and Australia are shipped in sailing vessels on account of lower freight rates.

Until recently, the machines sent to foreign countries were of the plainer styles, but within the last year or two, there has come a demand for handsomer frames and cabinets, and the average price paid has increased correspondingly.—New York Sun.

THE SHEATHED PROPELLER.

Since the introduction of steam navigation, traffic by sea has undergone as great changes as that by land has experienced since the opening of the first railway line. It has long been a problem to find some suitable contrivance by which sailing vessels might, in times of calm or of contrary winds, by the help of auxiliary engines, continue their course.

THE PROPELLER UNSHEATHED.

THE PROPELLER READY FOR USE.

Most freight vessels carry both sails and machinery nowadays, but we need not consider these, as the subject of our article concerns smaller craft only.

The Sheathing Propeller Company, of London, has lately put on the market a small propeller of peculiar construction. Our two illustrations, which we have borrowed from Der Stein der Weisen, will serve to show its construction. We see in the first cut the usual semicircular opening in the rudder and the propeller shaft emerging from a steel casing. The propeller itself is not set in position for use, but the two wings or blades are folded in an axial position. To make this possible they are hinged in a spherical head, which, on the side furthest away from the ship, has a slot permitting the two blades of the propeller to move in a plane extending longitudinally of the shaft. In our second cut we have the propeller opened, ready for use. When the ship is sailing by wind or is at rest the whole contrivance can be drawn back into the tubular casing of the shaft. The same company also makes a somewhat similar propeller which is, however, drawn in fully opened into a receptacle of corresponding dimensions. But this modification offers far less advantages. The first objection is perhaps the considerable space required, which might of course be used for other purposes. Besides, when the propeller is not in use, it causes quite an appreciable resistance, which, of course, lowers the rate of progress attained under sail.

But the first mentioned form will certainly be found most useful by many classes of ship owners.

Sportsmen will, no doubt, object to having on board machinery of any sort, be it only a small benzoline motor. But for fishing smacks, small merchant sail-

ing vessels, and even for large steamers, the folding propeller will be a very advantageous acquisition.

Hitherto steam has been useless as a means of propulsion to fishermen, as the screw or paddle would get caught in the nets and ropes, and not only foil all attempts at pursuing their business, but cause considerable trouble, and perhaps some danger. Such difficulties are avoided by the propeller shown in our cut.

We stated above that it would also be of great use to smaller merchant vessels constructed to carry sails. Such are usually supplied with some machinery for loading purposes, for hoisting sails, moving heavy articles, etc., and these engines would be quite sufficient to work the light propeller; so that the danger of a stoppage in a dead calm, and the commercial loss in such cases, would be avoided. But even if there is no steam power on board, a small motor of any description will do the work quite satisfactorily, and the owner would have an almost unlimited variety to pick from.

As for the advantage gained by providing large steamers with one or several such propellers, it will occur to every one who calls to mind the difficulties that our large vessels have in landing and coming alongside the docks or piers. The cause of all this trouble is that, when the boat is nearly stopped, it no longer obeys the rudder, and so towing has often to be resorted to. If, besides the main propeller, there were two smaller screws, one on each side, this difficulty would be overcome. For, by working only one of them, a curved course might be given to the boat. Besides, of course, there is always a possibility of damage to the main propeller, and in such emergencies the sheathed screws would of course be resorted to. It is also said that the lurching and rolling of fast running boats could to a great extent be mitigated by the use of two auxiliary screws.

The sheathed propeller would then be used with great advantage on all kinds of craft—the fishing smack, merchant sailing vessel, passenger and freight steamer, and even the man-of-war would each be benefited in her own way.

All parts of the screw which come in contact with sea water are made of bronze, gun metal and other appropriate alloys. The company has constructed models of ships fitted with their propeller up to several horse power, providing the inquirer with plans, information and directions concerning the use and installation of its goods.

THE NEW BRIDGE OF ST. LOUIS AT SENEGAL.

A NEW metallic bridge has recently been completed over the River Senegal, replacing the old wooden pontoon bridge established by General Faidherbe. Both bridges are distinctly shown in the illustration published herewith, for which we are indebted to Le Monde Illustré. The old bridge is a flimsy-looking affair, which might be readily carried away by even a moderate flood. The last section of the new bridge is ready to be floated into position.

The bridge is 600 meters long and was built by the Nogier & Kesler Company, to whom the work was allotted by the Committee on Adjudication. The contract price was 1,500,000 francs.

The illustrations present an interesting contrast of the latest type of bridge construction as compared with the primitive efforts of an earlier date.

THE NEW BRIDGE OF ST. LOUIS AT SENEGAL.

COMMON SENSE AND SCIENCE.

HERR VON MEYENBURG, a Swiss engineer who has been making a tour of the machinery manufacturing centers of the United States, visited Worcester, Mass., and gave a representative of a paper an interview of some length on the things he had observed about the quality of American mechanical genius and of American machinery. Among other things he said: "My object in coming to this country is to buy machinery and thoroughly to investigate the design and construction of American machine making tools. In machine-tool construction America beats the world. The finest lathes, planers and all tools used in the manufacture of other machines can be bought in this country. Foreign manufacturers are beginning to realize this and to buy largely in this country. But on the other hand, the machines and engines which are made with the American labor and with the American tools are vastly inferior to those made in Europe. Some of your finest engines, dynamos, and other machines would not hold a place in the German or Switzerland market any time at all. Your tools are better, but the machines are inferior. It is partly due to the labor, and partly to the men in charge. Labor is so costly here that for the same money you cannot get out equally good machines. You make them too fast, and the finish and construction are not so fine nor so accurate. Then, too, your foremen and master mechanics do not get the training that ours do. I do not want to criticise any one American mechanical school, for they are all alike. A student goes through a course of four years and then is ready to take up his work. In the meantime he has taken a general course in theory and, in addition, has had a smattering of the practical work, a little blacksmithing, a little lathe work, a little welding and a little something else. None of it is complete. In our schools we have a four year course in theory. During that time we do not have a bit of work in the shop, but we study the theory very carefully. We are made to think, instead of gathering a mass of tables and figures in our heads indiscriminately. At the end of the four years we go into the shop and have two years' work there. Then we are ready to take a position.

"As a result, the German master mechanics have a tremendous amount of knowledge and the power to apply it in special cases. But we lack the common sense and personal energy that you have in this country. You have the common sense and quick wittedness, but lack the knowledge of the great principles. It is not the teachers' fault. You have fine teachers here; but the Americans don't want to learn; they don't think. They would rather 'sport,' I think you call it. You don't learn the languages carefully. You think that America beats the world in everything, and that there is no need of studying foreign methods. Now, there are some excellent things in Germany, which can be found out only by reading the original description in German. The reason why American tools are better, while the better machines made with them are found in Europe, is this: Machine-making tools do not involve the great principles that engines, dynamos and great machines do. Tools are really evolved. If a piece is found by experience to be too small, it is made heavier next time. Tools start at a simple stage and are gradually evolved step by step. You, in this country, apply your common sense and make the changes as a matter of course and without much thought, while a German would spend a long time in figuring out the why and wherefore, and would be distanced by his American competitor. In the greater tasks thorough and complete knowledge of the great principle is necessary. Manufacturing interests are greatly on the increase in Europe, and machine tools are being bought in great quantities. It is a great opportunity for the American manufacturers of tools, for the European market cannot supply the demand, and the European manufacturer prefers the American product if he can get it. The American goods are being exported largely, and that is what keeps your machine tool shops so busy in general dullness of trade. The opportunity may not last forever, though, for some time we will get the required common sense, and when we do, our machine tools will be better than yours."

While Herr Von Meyenburg may be partly right, he is evidently partly wrong, and what he says is self-contradictory. Machines are made in accordance with principles. Science is a knowledge of those principles. The mechanics who make the best machines must surely possess more real science than other mechanics who do not make similar machines so well. The over-taught European may have more "theory" than the American engineers, who, he alleges, are undertaught, but he confesses that the undertaught Americans turn out machines that surpass the best products of the overtaught Europeans. If he means anything by this apparently illogical situation, he means that what he calls a "smattering," or too little technical training, is far more desirable and efficient mechanically and commercially than too much technical training, which, according to his view, has stifled "common sense" and dulled the conceptions and perceptions of the unfortunate Europeans subjected to a surfeit of theories. Nor is he any clearer or more convincing in what he says about the products turned out by American and European mechanics. A close comparative study of American and European products in the Columbian Exposition in 1893 absolutely failed to show the European superiority in fineness of work, elegance of design, solidity of construction or perfection of function which Herr Meyenburg claims. Prominent critics awarded the palm of superiority to the American exhibitors there. The German wood and iron working machines shown were models of ugliness and awkwardness, which no American shop would accept as a gift under the provision that they must use them. More than one European engineer, who came to the United States heralded by a great blare of trumpets to revolutionize mechanical work here and show the natives how to do it, has utterly failed, and has either returned to Europe, where "theory" stands in higher regard than "common sense," or else is occupying some obscure position here. It would be unkind to mention specific cases, but we are not willing to let pass such assertions as those of Herr Meyenburg without a comment. The American system of training may have its defects, but certainly it has in it no defect that implies the smother-

ing of common sense. The European system of training may have no defects, so far as it goes, but evidently it needs to go further, and, instead of submerging its victims under a flood of inapplicable theory, have added to it the elements needed to arouse the sleeping "common sense" of men whose work, above all things else, is the embodiment of common sense in tools and machines. Herr Meyenburg reasons or unreasons himself into an illogical situation which is a queer commentary on the lack of "common sense" which he so bemoans in the Europeans in general. His elucidations do not elucidate.—American Woodworker.

MOUNT VERNON, MO., July 16, 1897.

To the Editor of the SCIENTIFIC AMERICAN:

DEAR SIR: I inclose in another package two pieces of glass water tube from the engine and boiler of the flour mill at this place. These are taken from the upper ends of the tube. The engineer has followed his business for about thirty-five years and tells me that this place is the first in which the tops of the tubes have eaten away in the manner shown. He says the water here gives no trouble in the boilers, but that the tubes, unless removed, will blow out in about two months, and all will show the same action in eating or wearing away. The packing and shape of the connections with the boiler is of the ordinary kind. We would like to know what is the trouble, and whether the action is a chemical or mechanical one. Observe that the enamel is gone on the outside and above the gum packing, and the inside of both tubes grooved lengthwise. Why does it eat away the outside of the tube first? The water end of the glass is not affected. There is no current of steam or water passing over the end affected.

The engineer and myself both take your paper, and if you will be so kind as to give us a little light on this subject, you will relieve two very puzzled people.

E. M. ESSEX.

[The subject of your query is explained in the following article by Mr. G. D. Hiscox.—ED.]

CORROSION AND BREAKAGE OF WATER GAGE GLASSES.

By G. D. HISCOX.

THE uncertain quality of water gage glasses and their liability to crack and burst is always a source of apprehension with engineers and firemen. The most important part of a water gage is the glass tube, and upon the perfection of its make and composition depends the confidence with which it is viewed. The defects arise principally from the composition and imperfect annealing, which leaves an unequal strain upon their outer and inner surfaces. Another defect is the gradual weakening of the tube by the solubility of the glass in pure water at the high temperature due to the pressure of steam carried in the boiler.

Before the introduction of the Scotch kelp glass tubes to the American market, water gage glasses were made from tubing of Bohemian, crown or flint glass, as convenient; their durability being very uncertain from the brittleness of the Bohemian glass under changes of temperature and the extreme solubility of the flint glass in contact with high pressure steam. The crown glass was better, but could not always be had in tubing. The introduction of the Scotch kelp glass tubes has made the conditions of breakage and wear more uniform, but with no apparent gain in the soluble properties of the glass.

Thus, by a series of experiments, flint glass has been found readily soluble under a pressure of from 300 to 600 pounds per square inch, at a less temperature than that of boiling water; other experiments have shown that pure water as it condenses from steam at high temperatures and pressures is an active solvent of glass in a degree dependent upon its composition, the greatest affinity being toward the kind of glass containing the greater portions of potash or soda.

Several theories have been named to account for the wearing away at the top and the streaks down the inside, which generally terminate at the water level of the gage glass. Friction of the water of condensation carrying particles of iron, rust and dirt is the most plausible, but it does not account for the cutting away of the outside of the tube at the top, where it projects above the rubber packing and into the chamber of the water gage head. This projection forms a small cistern around the top of the tube, which is a receptacle for the water of condensation on the inner surface of the gage head at a constant temperature and pressure due to the boiler pressure, and which is constantly filling and overflowing and running down the inside of the tube. There being no friction worth consideration in the little cistern around the top of the tube, the only tenable theory for so great a waste of glass at this point must be found in the soluble power of pure water at the temperature and pressure in the boiler, and that pressure is the potent influence in the process. In support of this last point, we may point to experience with low pressure heating apparatus, for gage glasses that have been in use for several years on low pressure boilers of less than five pounds pressure have been removed with scarcely a mark of corrosion.

The cracking of water gage glasses may be mainly attributed to the tension of the glass on the inside surface by faulty annealing, as this is shown by the fact that a slight scratch around on the inside surface at the proper place will produce a crack following the scratch. This is the method used for breaking the tubes to the proper length for use, while if the scratch is made on the outside of the tube, it does not crack at the scratch naturally, and if pressure or a light tap is used to start the crack, it will break just where not wanted. This very plainly shows that there is compression on the outside and tension on the inside surface of the tube.

This is also manifest in the care necessary in cleaning the tubes by wiping, as every engineer knows by teaching or experience of the final cracking or splitting of the tube when an iron rod or wire is used for pushing the wad through the tube. Unless the whole rod is wound with a strip of cloth to prevent scratching, the contact from a scale or particle of grit may make a scratch that cannot be seen by the eye, but will soon split the tube when exposed to changes of temperature in the water gage. In this way a very curious phenomenon has been observed in the cracking of tubes in a spiral line for the greater part of their length. The cause of this has been traced to the fact that the construction of the water gage heads sometimes produces a whirl in the steam inside of the glass when it is blown off at the bottom. Any scale or other hard substance from the inside surface of the top connecting pipe partakes of the whirling motion of the steam, and the centrifugal force presses the particles against the inside surface with a sufficient force to produce a spiral scratch not noticeable at the time, but soon starts a crack that, as has been observed, ran on a spiral more than once around the tube.

Another source of trouble by breakage is from unequal expansion between the glass and the ironwork, especially if the water gage heads are screwed directly into the shell of a vertical or locomotive boiler. The expansion and contraction of the boiler plate is about 40 per cent. greater than that of glass for even changes of temperature; but as the glass tube below the water line may be somewhat cooler than the boiler plate, the difference in expansion may be greater than here stated. This strain constantly changing from day to day or week to week, presuming that the rubber packings have become hard or vulcanized to the glass, as is often the case, the contact becoming closer and with a longer bearing, from the screwing of the stuffing boxes too tight at first, or following up the cap to stop leaks, makes an immovable connection between the glass and the gage head that finally throws the whole strain from expansion upon the tube, which, with the natural tension upon the inner surface, pulls the tube apart.

When water gages are placed on columns of cast iron free from contact with the boiler, except by their connecting pipes, and care is used in squeezing the rubber packing rings lightly or only just enough to prevent leakage, there is far less trouble from breakage. By this arrangement the cast iron column is kept slightly cooler by the slower circulation of the inclosed water, and the cast iron also having a slightly less expansion than wrought iron for given changes in temperature, makes this method of water gage connection much the most reliable for safety as well as the steadiest indication of the water level in the boiler.

Where water gages are connected to the cast iron front with pipe connections to the boiler, corrosion of the gage glass seems to be largely increased, as observed, and also from the fact of the increased flow of hot water and iron rust through the glass from condensation in the usually bare pipe from the boiler. This is relieved in a great measure by the use of the independent stand pipe, which should be required by purchasers of boilers of any style in use.

FLOATING GRAIN ELEVATOR.

WE illustrate herewith a grain elevator constructed by Messrs. S. S. Stott & Company, of the Laneside Foundry, Haslingden, near Manchester, a firm which has long been associated with this type of engineering. This elevator was made for Russia, the grain being taken from one barge and passed into one of either of several barges lying alongside each other. In both cases the apparatus is on the endless chain and bucket system, the series of elevators is the same, although in the latter instance the grain is deposited in a "boot," and conveyed thence to the barges; in the other it is again raised and discharged by conveyor and gravitation into a ship's hold. The trestle shown in the engraving usually runs on rails laid on a barge 12 ft. or so wide; hence the name, a floating elevator. The boiler for supplying steam to the engine driving the elevators and conveyors is placed on deck or between decks; but this is a matter of arrangement according to requirements.

The framing of the trestle consists of T and angle irons with cross and diagonal stays, and it is carried on 18 in. wheels running on rails. The system of conveyors will at once be appreciated from the engraving. The grain is elevated from the barge which is supposed to be moored to the left of the engraving, carried along a conveyor, and discharged through a shoot into a boot at the bottom of the trestle, is thence raised by another elevator discharging through a telescopic shoot into the hold of the vessel. The apparatus illustrated has an overhang of 20 ft. into the barge. The elevators are extended from the outer ends of a pair of derrick arms. The elevator for the apparatus to discharge 60 tons per hour has buckets 15 in. long; for the machine delivering 100 tons per hour they are 18 in. long. They are carried by double lines of detachable link chain, 9 in. to 12 in. apart. These chains are operated by sprocket wheels at either end; these rotate in gun metal bearings secured to the sides of the elevator trunk or casing, built up of timber with steel bracing and angle irons. The tension on the chain is provided by a screw and nut fitted to the bottom bearings. For this purpose the bearings on either side are fitted into sliding frames 12 in. long, and through each there is a square threaded screw for the purpose of making the chain taut. At the top of the screw there is bevel gear to connect the screws on either side, so that both will act simultaneously. Inside the trunk the chain guides are of timber faced with steel, which can easily be renewed. At the bottom there is a 2 in. steel grid to prevent the buckets being damaged.

The grain is delivered from this elevator through a small hopper into the conveyor leading to the boot in the bottom of the trestle. To insure a readier delivery, there is a guide or backing pulley just under the point where the elevator tips its load. The conveyor is 20 ft. long. This determines the amount of overhang of the elevator so far as the barge is concerned. The band conveyor is supported on two wrought iron derrick arms of channel sections, with trunnions on each end, so as to swivel at both ends. These are supported at the outer end by steel wire ropes passing over pulleys at the head of the trestle to a power-driven crab on the platform on the trestle. The trunnions enable the derrick arms and the barge elevator to be drawn up in a vertical position alongside the trestle when not in use. The inclination at which the conveyor between the derrick arms will work varies from 15 deg. in an upward direction to 30 deg. downward. The band conveyor consists of an endless band of cotton 21 in. wide, passing round pulleys at each end, and supported by intermediate steel rollers about 5 ft. pitch. Angle steel rollers are attached to the sides of the conveyor for giving the necessary curvature. The framing supporting the pulleys is of timber. When desirable, the grain is protected from the weather by means of tarpaulins carried on T-irons, which are shown in the engraving.

GRAIN ELEVATOR FOR RUSSIA.

The grain flows from the conveyor into a shoot built up of timber lined with steel, thence into the boot of the fixed vertical elevator carried upon the trestle. The elevator does not differ materially from the one which is suspended on the derricks for use in the hold of the barges. In the case of the 100 ton apparatus, it is able to discharge to a height of 25 ft. above water level, and even then the conveyor into the ship's hold might be placed at a slight upward angle, although obviously this would only be resorted to under exceptional circumstances. It is very unusual to find a ship with her fixed bulwark more than 25 ft. above water level. The telescopic shoot, or conveyor, into the hold of the ship, as the case may be, is also arranged to swivel fore and aft; but this necessitates in the case of a belt conveyor somewhat elaborate gear. This swivel gear is fixed to the side of the trestle, and consists of a cast iron frame with bevel and spur gearing. The sprocket wheel for driving the belt first actuates a horizontal shaft which through bevel gearing and a vertical shaft finally rotates a second horizontal shaft. This latter by spur gearing actuates the end shaft carrying the traveling drum around which the

belt travels. Thus the two horizontal shafts need not be parallel, the vertical shaft transmitting motion from the first horizontal shaft to the conveyor. This conveyor is usually about 25 ft. long in both 60 and 100 ton apparatus. Sometimes, as we have said, there is substituted a telescopic shoot constructed of steel plates, and about 30 ft. long, opening out in 10 ft. lengths. This, of course, can only be used when the vessel is lower than the top of the trestle of the conveyor.

Two 60 ton machines are not infrequently mounted upon one barge, in which case the power plant consists of a horizontal multitubular boiler, 7 ft. 6 in. in diameter by 7 ft. long, furnishing steam to two small horizontal steam engines, each with two cylinders, 7 in. bore by 12 in. stroke, the actual power required for both machines not being more than 20 indicated horse. The 100 ton machine is driven by a horizontal steam engine with two cylinders 9 in. bore by 15 in. stroke, steam being supplied by a horizontal multitubular boiler, 7 ft. in diameter by 7 ft. 6 in. long. The actual power required for driving a 100 ton machine is not more than 15 indicated horse. The engine drives a shaft with bearings on the deck of the barge, and extending the whole length of the railway on which the trestle is traversed. Power is transmitted from this shaft by wheels and detachable chain to a second shaft, fixed as shown on the traveling trestle. Similar chain gearing drives the shaft on the derrick arms, whence power is derived for the swiveling of the derricks, for driving the conveyor and the bucket chains of the elevator, as well as of the fixed elevator. Detachable chains are used in all cases, and where there are vertical drives tension wheels are introduced. For driving the fixed elevator power is taken from the same shaft to a shaft at the top of the trestle, which also drives the conveyor, extending over to the hatch of the ship. The sprocket wheels are all of steel. Inside the elevators the chain is of 2½ in. pitch in the case of the 60 ton apparatus and 3 in. in the 100 ton plant. The drive chain is 3 in. pitch, but the main drive from the engine shaft is 3½ in. pitch. The chains in the 60 ton elevator are constructed for a working strain of 850 lb., and in the 100 ton machine 1,500 lb.

On a platform of the trestle is a crab driven by two belts from the main shaft, so fitted as to give reversing motion, with one fast and two loose pulleys. All the wheels are of steel, the bearings of gun metal; sprocket gear is preferred, as it is unaffected by weather. All timber subject to the wearing action of the grain is steel-lined. The trestle wheels are driven by spur and pinion gear; the gage is usually 10 ft., and there are four wheels. The barges themselves are from 60 ft. to 100 ft. long, from 15 ft. to 20 ft. wide and about 10 ft. deep.

A special feature is that the apparatus is bolted to the deck, and that the grain is conveyed from one barge to another or on shore; and thus, instead of the band conveyor from the movable elevator, there is a steel telescopic shoot delivering into a hopper under which there passes a band conveyor which is led to the barge or on shore. The distance the grain may thus be conveyed is not limited, as several belt conveyors can be laid one under the end of the other. The order carried out by Messrs. Stott in this case was for conveyors to traverse 95 ft. from the foot of the elevator.—Engineering.

PHOSPHOR BRONZE.*

By Max H. Wickhorst.

Bronze is an alloy of copper and tin. Phosphor bronze is bronze containing varying amounts of phosphorus, from a few hundredths of 1 per cent. to 1 or 2 per cent. Bronze containing simply copper and tin is very liable to be defective from the presence of oxygen, sulphur, or occluded gases. Oxygen causes the metal to be spongy and weak. Sulphur and occluded gases cause porosity. Oxygen gets into the metal by absorption from the air. It can be eliminated by adding to the metal something which combines with the oxygen and then fluxes off. Such deoxidizers are zinc, antimony, aluminum, manganese, silicon, and phosphorus. Sulphur and occluded gases can be eliminated by melting the metal, exposing it to the air and letting it thus absorb some oxygen, which then burns the sulphur and gas. The oxygen can then be removed by adding one of the above-mentioned deoxidizers. The important use of phosphorus in bronze is therefore to remove oxygen and also indirectly to destroy occluded gas and sulphur.

At the C., B. and Q. R R. brass foundry, at Aurora, Ill., we make a bronze with an extra high percentage of phosphorus, namely, 6 per cent. We make this alloy so as to have phosphorus in convenient form for use, and the process of manufacture followed by us is as follows: 90 lb. of copper are melted under charcoal in a No. 70 crucible, which holds about 200 lb. of metal when full; 11 lb. of tin are added and the metal is allowed to become hot. The crucible is then removed from the furnace and 7 lb. of phosphorus are introduced in the following manner: A three-gallon stone jar, half full of dilute solution of blue vitriol, is weighed. Then the weights are increased 7 lb., and phosphorus in sticks about 4 in. long is added till the scales balance again. The phosphorus is left in this solution half an hour or longer, the phosphorus being given a coating of copper, so that it may be dried and exposed to the air without igniting. We have ready a pan about 30 in. square and 6 in. deep, containing about 2 in. of water. Over the water is a wire netting, which is laid loose on ledges or supports along the inner sides of the pan. On the netting is blotting paper, and on this the phosphorus is laid to dry when taken out of the blue vitriol solution. The pan also has a lid which can be put down in case of ignition of the phosphorus.

We now have the phosphorus ready for introduction into the metal. This is done by means of a cup-shaped instrument called a retort or phosphorizer. One man holds the retort on the rim of the crucible in a horizontal position. A second man takes about three pieces of phosphorus and throws them into the retort. The first man then immediately plunges the mouth of the retort below the surface of the metal before the phosphorus has a chance to fall or flow out. Of course the phosphorus immediately melts and also begins to volatilize. As the phosphorus comes in contact with the metal, it combines with it. This process is continued till all the 7 lb. of phosphorus has been put into the metal. The metal is then poured into slabs about 3 in. by 4 in. by 1 in. thick. The metal is so hard that a greater thickness would make it difficult to break it up. When finished, the metal contains, by analysis, 6 per cent. of phosphorus. When we wish ordinarily to add phosphorus to metal, we do it by adding a little of this hardener.

Copper is a soft, ductile metal, with its melting point at about 2,000 degrees Fah., or 1,100 degrees Cen. Molten copper has the marked property of absorbing various gases. It is for this reason that it is so difficult to make sound castings of clear copper. Molten copper combines readily with the oxygen of the air, forming oxide of copper, which dissolves in the copper and mixes homogeneously with it.

A casting made from such metal would be very spongy. The bad effect of oxygen is intended to be overcome by adding zinc to the extent of 1 per cent. or more. This result can be much more effectively attained by the use of aluminum, manganese or phosphorus. The action of these substances is to combine with the oxygen, and as the product formed separates and goes to the surface, the metal is left in a sound condition. Aluminum and manganese deoxidize copper and bronze very effectively, and the oxide formed goes to the surface as a scum. When a casting is made from such metal, the oxide or scum, instead of freeing itself from the casting perfectly, generally remains in the top part of the casting mixed with the metal, as a fractured surface will show. Phosphorus deoxidizes copper, and the oxide formed leaves the metal in the form of a gas, so that a casting made from such metal shows a clean fracture throughout, although the metal is not as dense as when aluminum or manganese is used.

Copper also has the property of absorbing or occluding carbon monoxide. But the carbonic oxide thus absorbed is in a different condition from the oxygen absorbed. When oxygen is absorbed by copper, the oxygen combines chemically with the copper and loses its own identity as a gas. But when coal gas is absorbed by the copper, it keeps its own physical identity and simply exists in the copper in a state of solution. All natural waters, such as lake water, river water, spring water, etc., contain air in solution or occlusion. When such water is cooled and frozen, just at the time of changing from the liquid to the solid state, the dissolved gas separates and forms air bubbles, which remain entangled in the ice. The carbonic oxide which is dissolved or occluded in copper acts in exactly the same way.

Hydrogen acts in exactly the same manner as carbonic oxide. Sulphur also has a bad effect on copper and bronze. Sulphur combines with copper and other metals, forming sulphide of copper, etc. When molten copper or bronze containing sulphur comes in contact with air it absorbs some oxygen, and this in turn combines with the sulphur present, forming sulphur dioxide, which is a gas which remains occluded in the metal.

Tin is a soft white metal, melting at 440 degrees Fah., or 230 degrees Cen. Toward gases it acts something like copper, but not in so marked a degree. Although copper and tin are both soft, yet when mixed they make a harder metal. When bronze cools from the molten state, the copper and the copper tin alloy tend to crystallize by themselves. The quicker the cooling occurs the less separation will there be, and also the fracture will be more homogeneous in appearance.

Gun bronze contains copper and tin in the proportion of 9 or 10 parts of copper to 1 of tin. This is the metal used where an ordinary bronze casting is wanted. A harder bronze is copper and tin in the ratio of 6 to 1. This is often used as a bearing metal. When either of these metals is to be turned in the machine shop, they should contain about 3 per cent. of lead, which will make them work very much better, but it also decreases their tensile strength. Bearing metal now generally contains about 10 per cent. of lead, with copper and tin in varying ratios. The large percentage of lead is put in that the metal may wear away slower. Lead, although a metal having properties similar to tin, acts entirely different toward copper. Copper and tin have a good deal of affinity for each other, but copper and lead show no attraction at all for each other. Copper and tin mix in all proportions, but copper and lead mix only to a very limited extent. About 3 per cent. of lead can be mixed with copper. With bronze about 15 per cent. to 20 per cent. of lead can be mixed. In bearing bronze the lead keeps its own physical properties, so that the constituent lead melts long before the metal attains a red heat. It sometimes happens when a bearing runs warm that the lead actually sweats out and forms pimples on the metal. Or sometimes in re-melting a bearing bronze casting the lead may be seen to drop out while the metal is warming up. All of these metals, however, should contain something to flux or deoxidize them, such as zinc, manganese, aluminum, silicon, antimony or phosphorus.

The phosphor bronze bearing metal in vogue at Aurora has the following composition: Copper, 79·7 per cent.; tin, 10 per cent.; lead, 10 per cent.; and phosphorus, 0·3 per cent.

Melt 140 lb. of copper in a No. 70 pot, covering with charcoal. When copper is all melted, add 17½ lb. of tin to 17½ lb. of lead, and allow the metal to become sufficiently warm, but not any hotter than is needed. Then add 10 lb. of "hardener" (made as previously described) and stir well. Remove from furnace, skim off the charcoal, cool the metal with gates to as low a temperature as is consistent with getting a good casting, stir well again, and pour. The moulds for this kind of work are faced with plumbago.

There are several firms that make phosphor bronze bearings with a composition similar to the above one, and most of them, or perhaps all, make it by melting the metals and then charging with phosphorus to the extent of 0·7 to 1·0 per cent. But I have found some metal from all brands that I have tried that contains occluded gas. So that after such metal is cast, in about two minutes or so, the metal will ooze or sweat out through the gate, and such a casting will be found to be porous. But I have not yet had one such experience with metal made as I have described above. My explanation for the imperfections of metal made by adding phosphorus direct to the final mixture containing occluded gas would be this: The phosphorus as it is charged into the metal still contains a little moisture, and at the high temperature of the molten metal the phosphorus takes the oxygen from this water, leaving the hydrogen to be absorbed by the metal.

But this practical point should be heeded, viz., that pig phosphor bronze should be brought to the specifications that the metal should have shrunk in the ingot mould in cooling, as shown by the concave surface of the upper side, and that it should make a casting in a sand mould without rising in the gate after being poured.

In bearing metal, occluded gas is very objectionable, because the gas, in trying to free itself, shoves the very hard copper tin compound (which has a low melting point and remains liquid after the copper has begun to set) into spots, and thus causes hard spots in the metal.

Phosphorus is very dangerous to handle, and there is great risk from fire with it, so that many would not care to handle the phosphorus itself. But phosphor copper containing 5 per cent. of phosphorus, and phosphor tin containing 2 to 7 per cent. of phosphorus, and several other such alloys can be obtained in the market. I would suggest to those who wish to make phosphor bronze, but do not want to handle phosphorus itself, to make it by using the proper amount of one of these high phosphorus alloys. In using phosphorus it is only necessary to use enough to thoroughly deoxidize the metal, say 0·3 per cent. More than this will make the metal harder, but not any sounder.

In the course of the discussion Mr. Wickhorst stated that phosphor bronze shrinks very little. He expressed the belief that the pure copper castings used in electrical work are made with the aid of silicon copper.

* A paper read before the Western Foundrymen's Association, Chicago, March 17, 1897.

THE FIRST ENGLISH ARMOR PLATE ROLLING.

In a sketch of the life work of Sir John Brown, the eminent English iron and steel manufacturer, The Engineer gives the following account of the first armor plate rolling in England:

"It is Mr. Brown's custom to go on the Continent every autumn. In 1860, on his way home, he returned by Toulon. There was no little commotion in the place that day. The French ship La Gloire had put into the harbor. This ship was a wooden 90 gun three decker. The French had cut her down into a sort of magnified corvette, armed her with forty heavy guns, and clothed her with hammered iron armor 4½ inches thick; the plates were each five feet long and two feet wide. This 'new departure' in men-of-war put our admiralty in a fever. Ten 90 gun and 100 gun timber built ships were at once stopped in their construction, the intention being to make them so many British editions of the French craft. Sir John tried to get on board the ship. He was not allowed. Inspecting the vessel very closely through his glasses, his quick eye detected that the hammered armor had a cobbled look, rough, like a rubble wall. He felt sure he could do better than that. Convinced that he could roll a plate superior to anything that could be hammered, he went back to Sheffield and set to work. He put down a rolling mill, and experimented incessantly until he achieved his purpose. At a meeting of the Institution of Mechanical Engineers, Sir John read a paper, in which he gave a description of the method of rolling a five ton armor plate. As the first authoritative account of armor plate rolling in England, an extract is worth preserving. Here it is: Several bars of iron were rolled twelve inches broad by one inch thick and were cut thirty inches long. Five of these bars were piled and rolled down to another slab, and these two slabs were then welded and rolled down to a plate 1½ inches thick, which was sheared to four feet square. Four plates like that one were then piled and rolled down to one plate, measuring eight by four feet and two inches thick. Lastly, four of these were piled and rolled to form the final and entire plate. There were thus welded together sixteen thicknesses of plate, each of which was originally one inch thick, to form one plate 4½ inches thick, being a reduction of thirty five times in thickness, and in the operation from 3500 to 4000 square feet of surface had to be perfectly welded by the process of rolling. Even with the greatest care it was not surprising that blisters and imperfect welding should occur and render the plate defective. This was the chief difficulty to be overcome, and it increased with the magnitude and weight of the plate, the final operation of welding the four plates, measuring eight by four feet and 2¼ inches thick, being a very critical one. The intensity of the heat thrown off was almost unendurable, and the loss of a few moments in the conveyance of the pile from the furnace to the rolls would be fatal to success."

The Chicago Trade Bulletin says: "From present indications the United States will raise the largest yield of wheat in many years, and probably the finest crop harvested by any country in 1897. The yield, while liberal, will probably fall below the quantity reported in 1891, but the outlook now favors the second largest yield ever reported. The winter wheat crop is virtually out of danger, and the spring wheat crop, with a backward and unfavorable start, owing to unseasonable weather, is now reaching maturity in good condition, though it will not be out of danger of the changeable weather of the Northwest for four or five weeks. It is virtually safe, unless some damage should occur, to calculate that the aggregate yield will approximate about 550,000,000 bushels, about 310,000,000 bushels of winter and 240,000,000 bushels of spring. At the same time, it is doubtful if the Department of Agriculture will reach such conclusions. The grain trade is confident that the area reported by the Department of Agriculture is too small, possibly by 2,000,000 acres, and this is the weak feature in the returns to the department. The deficiency is largely in the new sections of the country which have been opened up through the agencies of railroads and the land disposed of to emigrants. These people, as a rule, are indifferent about making reports, and have a dread of a crop reporter, regarding him as an agent of the assessor in disguise."

ENGINEERING NOTES.

In some of the American car shops the journals for car axles are now turned up by means of a tool extending the whole length of the journal and accurately ground to the proper shape. The cut is thus several inches wide.

It is interesting to note that the capital value of the British Navy at the present time exceeds 94,000,000 pounds. The first cost of the fleet which led to the downfall of Napoleon was but 10 millions sterling. The fleet then comprised between 480 and 490 fighting vessels.

There are now in operation in the United Kingdom 380 blast furnaces, as compared with 372 at the beginning of the year, says Engineering. Of the total 95 are in the northeast of England, 179 more in other parts of England, 81 in Scotland, and 23 in Wales. There are, however, 682 furnaces actually built, so that 302 are not in blast. At the beginning of the year there were 313 idle. Five new furnaces are being built and five are being rebuilt.

Some interesting data have been collected by Mr. F. P. Sheldon, of Providence, R. I., intended to show the actual cost of steam power in New England and New York cotton mills. The results are based on actual yearly accounts, not on tests or calculations, and the cost per horse power per year of 307 days, of ten hours each, is found to be less than the common estimation. Compound condensing engines were used, and the highest running expenses—that is, fuel, labor, supplies, and repairs, also including fixed charges—show a total yearly cost per horse power of $14.80, and the lowest running expenses and fixed charges $11.64. In the highest cases given, fuel cost is stated as amounting to $3 a gross ton; in the lowest, mixed dust and slack costing $1.76 a gross ton was burned.

Mr. Thomas Fletcher, says Engineering, has recently published an estimate of the amount of coal gas needed to maintain an ordinary small fire clay muffle at the proper temperature for various purposes, and using the gas in atmospheric burners. For hardening steel cutters, etc., which requires clear red heat, about 8 cu. ft. of gas per hour are needed for every 10 sq. in. of floor area of the muffle. A yellow such as needed in silver assay work requires a consumption of 10 cu. ft. of gas per hour, while the bright yellow used in gold assays requires about 11 cu. ft. per hour. For still higher temperatures, such as needed in china, enamels, etc., the consumption may go up to 14 cu. ft. of gas per hour for every 10 sq. in. of the floor area of the muffle. Where metal muffles can be used, or the gas can be burned under pressure, a smaller consumption is needed.

The copper production of the world for 1896 is thus given in Le Génie Civil:

Country.	Metric tons.
United States	203,893
Spain and Portugal	53,375
Chile	23,500
Japan	21,000
Germany	20,063
Mexico	11,150
Australia	11,000
South Africa	7,450
Other countries	21,825
Totals	373,208

In 1888 the total copper production was 258,038 tons; in 1890 it was 310,472; 1893, 303,534; 1894, 324,505; and in 1895 it was 334,285 metric tons.

A model macadam road is being built at New Brunswick, N. J., by the road bureau of the United States Agricultural Department. Through the efforts of Prof. E. B. Voorhees, of the New Jersey Experimental Station, at New Brunswick, two government experts have been sent to supervise the construction and to bring with them the most approved machinery. The street treated is College Avenue, in the residential part of the city. The trap rock is crushed upon the ground, spread by an improved distributing wagon and laid to a depth of 4 inches. It is then rolled by a heavy steam roller and treated with a covering of cinders and a final coat of screenings. When this is completed, a 600 foot length of "farmers' cheap macadam" road is to be built. This road will be 8 feet wide and 5 inches deep. Road engineers and freeholders from various parts of New Jersey are closely watching the methods of construction.

Burning corn for fuel has often been mentioned by political orators as one of the signs that the poor farmer who burns it is in the last ditch of poverty, but a bulletin issued by the Experiment Station of the University of Nebraska, giving results of tests of the value of corn as fuel, shows that the burning of corn may be a proceeding showing financial wisdom and one greatly to the farmer's benefit when the price of corn is low and that of coal high. The tests showed that 1 lb. of screened Wyoming coal, costing $6.65 per ton, evaporated 1·9 times as much water in a steam boiler as could be evaporated by 1 lb. of a good grade of yellow dent corn on the ear, not thoroughly dry. The following figures show the value of corn per bushel as fuel when coal of the same variety as that used in the tests is selling at the prices given:

Coal per ton	$4.87	$5.41	$5.95	$6.49	$7.03	$7.57	$8.11
Corn per bushel	9	10	11	12	13	14	15

The calorific value of bagasse has recently been determined at the Ohio State University, and we are indebted, says the Engineering News, to Prof. W. T. Magruder, professor of mechanical engineering in that institution, for the following results of tests. Bagasse is the ground sugar cane, which is used by the sugar mills as fuel under steam boilers. The samples came from the Glenwild Sugar Factory, Berwick, La., and the tests were made with the Mahler calorimeter by Mr. Frank Haas, of the chemical department of the university. The moisture found in two samples, after drying to constant weight, was 44·13 and 44·38 per cent., average 44·26 per cent. The heating value of the dry bagasse, in three tests, was 4,542, 4,541 and 4,476 calories, or an average of 4,520 calories per lb., or 8,136 British thermal units per lb. This is equivalent to 4,535 B. T. U. for the moist bagasse containing 44·26 per cent. moisture.

ELECTRICAL NOTES.

Three interesting papers on transmission of power were recently read before the British Institution of Civil Engineers. Preece states that if coal costs only $1.25 per ton for transportation 100 miles, this is less than the interest on the capital required for construction of plant to transmit electrically, but other advantages of electric transmission are pointed out. Ellington writes on hydraulic transmission, and claims an efficiency of 75 per cent. over an area of 4 square miles, served from one pumping station, admitting, however, that this efficiency may drop to 50 per cent., depending on the application of the power. The third paper, by Hopkinson, refers to five methods of power transmission. He decides on compressed air as best for tunnel work, but recognizes the advantages of electricity in its flexibility. He also gives a prominent place to hydraulic transmission.

A new design of multiphase generator has been recently developed by the engineers of the General Electric Company, says the Engineering News, which is notable for the simplicity of its construction. This dynamo is a three-phase alternator with rotating fields and stationary armature, a design which so greatly facilitates the security of high insulation upon the armature that the dynamo can generate currents with pressures up to 5,000 volts. The machine is thus admirably adapted for long distance power transmission, as it dispenses with the necessity for step-up transformers in the power station. The rotating field has a substantial spider supporting a soft steel yoke ring magnetized by removable coils constructed to permit free ventilation. Current at low voltage is supplied to this field by two collector rings mounted upon the shaft. The armature coils are wound on forms and afterward placed about the poles, and thus a large portion of the coils remain exposed for ventilation. While these alternators have excellent inherent or self-regulating properties, they are sometimes compounded to insure accurate automatic regulation. Large generators of this type will be installed in the great Lachine Rapids plant, in the new Brooklyn Edison station, and in London, for the Central London Underground Railway.

Recent occurrences in Europe have brought out very clearly the growing use of electricity in warfare, says the Electrical Engineer. Naval experts at Kiel have been testing the practical uses of dragon-shaped airships or balloons, which may be put on board vessels for use during naval engagements and in reconnoitering. Some of the balloons rose 5,500 ft., remaining fastened to the decks of torpedo boats, which were steaming 18 knots an hour, enabling the balloonists to make valuable observations of the stations of vessels at a great distance. The observations made were communicated by telegraph or telephone from the balloons to persons on the decks of the vessels below, enabling them to change the course of the latter accordingly. At the British jubilee naval review the United States man-of-war Brooklyn received great attention; and Mr. Laird Clowes, the naval expert, declared that, as proved by the new ship, England is in the resort to electricity many years behind the United States. That she will remain so is seriously open to question, but credit for our leadership is welcome and must be ascribed to the patient and brilliant work of such men as Lieut. B. A. Fiske, who may be said to be devoting their lives to this subject, in behalf of our navy.

The Electrical Review does not regard vestibuled trolley cars with favor, and urges some practical objections to their employment. Commenting on the law passed by our last Legislature making it obligatory on all surface railroad corporations operating street cars in cities of less than 50,000 to run vestibule cars in the inclement winter months, it says: "If we are to judge by results elsewhere, the wisdom of such a law is doubtful, and its operation a useless expense to the railway companies. The glass front of the vestibule is the objection, for two reasons: It gets covered with frost, rain or snow or moisture, and becomes a serious obstruction to clear vision on the part of the motorman. It acts at night, besides, as a mirror, reflecting back the light thrown out from the car. So serious is this that in many cases the management has been compelled to hang a curtain across the car door so as to keep the vestibule dark, but it is a doubtful remedy. The general result of a vestibule law has been, we believe, to increase the number of accidents. If the law were amended to be something in line with the marine regulations compelling pilots to keep at least one window open to the air, most of the objectionable features would be eliminated and a higher degree of safety assured."

Long distance transmission has received quite a substantial impetus by the signing of a contract between the Southern California Power Company and the General Electric Company for an 80 mile electrical transmission equipment, says the Engineering News. This is really a remarkable step, and shows clearly that modern electrical machinery is reaching a very high degree of refinement. Previous to this the Ogden-Salt Lake City plant, in which power is transmitted a distance of 36 miles, held the record. The new California plant will be over three times as long, will transmit four times the power and will have a line pressure three times as great as the present Niagara Falls and Buffalo transmission plant. The power station will be located twelve miles from Redlands and will utilize the river running through the Santa Ana Canyon. The present plan is to draw water from this river at its junction with Bear Creek and convey it by means of suitable canals, tunnels and flumes along the canyon sides to a point where the riveted steel pipe line will begin. This will have a vertical fall of 750 ft. in its length of 2,200 ft. Four impact wheels will drive four General Electric three-phase generators, each of 750 kw. output, to which they will be directly connected. 250 kw. step-up transformers will raise the pressure to 33,000 volts. This unusually high line voltage is considered advisable owing to the very great length of the transmission. It will necessitate especial care in general insulation and line construction, but can be safely handled with present apparatus. Prof. E. M. Boggs, of the Arizona University, has been engaged as chief engineer for the Power Company.

SELECTED FORMULÆ.

Ink Eraser.—The following formulæ will be found effective and uninjurious to the paper if carefully handled:

Citric acid	1	part.
Water, distilled	10	"
Concentrated solution of borax	2	"

Dissolve the citric acid in the water and add the borax. Apply with a delicate camel's hair pencil, removing any excess of water with a blotter. A mixture of oxalic, citric and tartaric acids in equal parts, dissolved in just enough water to give a clean solution, acts energetically on most inks.—Canadian Druggist.

Dressing for Linoleum.—A weak solution of beeswax in spirits of turpentine has been recommended for brightening the appearance of linoleum. Here are some other formulas:

(1.) Palm oil	1	ounce.
Paraffin	18	"
Kerosene	4	"

Melt the paraffin and oil, remove from the fire and incorporate the kerosene.

Polish.

(2.) Yellow wax	1	ounce.
Carnauba wax	2	"
Oil turpentine	10	"
Benzine	10	"

Melt the waxes carefully, add the oil and benzine, and stir until cold.

(3.) Yellow wax	5	ounces.
Oil turpentine	11	"
Amber varnish	5	"

Melt the wax, add the oil, and then the varnish. Apply with a rag.—Pharmaceutical Era.

Perspirol.—For excessive perspiration of hands and feet:

Prepared Venetian talc	20	ounces.
Powdered orris root	10	"
Oxide of zinc	5	"
Powdered tartaric acid	5	"
Powdered boric acid	5	"
Salicylic acid	2½	"
Menthol	¼	"
Oil of eucalyptus	¼	"

Make a fine powder, to be applied to the hands and feet, or to be sprinkled inside the gloves or stockings.—Chemist and Druggist.

Compound Menthol Cones.—The following formula is given by Schimmel as representing a form of compound menthol cone which now finds widespread use:

Menthol, crystallized	1	part.
Chloral hydrate	1	"
Cacao butter	2	"
Spermaceti	4	"

The best way to prepare the cones is to melt the spermaceti and the cacao butter; dissolve the other ingredients in the melted mixture, and then pour the whole into chilled moulds.

Starch Glaze (Powder).—

Gum arabic, powdered	3	parts.
Spermaceti wax	6	"
Borax, powdered	4	"
White corn starch	8	"

Method of Preparation.—All these bodies are to be intimately mixed in the powder form by sifting through a sieve several times. As the wax is in a solid form and does not readily become reduced to powder by pounding in a mortar, the best method of reducing it to such a condition is to put the wax into a bottle with some sulphuric or rectified ether and then allow the fluid to evaporate. After it has dissolved the wax, as the evaporation proceeds, the wax will be deposited again in the solid form, but in fine thin flakes, which will easily break down to a powder form when rubbed up with the other ingredients in a cold mortar. Pack in paper or in cardboard boxes. To use, four teaspoonfuls per pound of dry starch is to be added to all dry starch, and then the starch made in the usual way as boiled starch.—Canadian Druggist.

Photographic Hints and Formulas.—

From Liesegang's Photographischer Almanach.—(Amer. Photo. Jl.)

Dr. Andresen's Eikonogen Formulas.—

(1) One solution:

Sulphite of soda (crystals)	4	parts.
Carbonate of potash	2	"
Eikonogen	1	"
Distilled boiling water	40	"

This mixture, while still warm, should be put into bottles, which must be well corked. It will then keep in good condition for an indefinite time, provided pure boiling water and a good quality of sulphite of soda have been used. Should the developer prove too strong, it may be diluted with a sufficient quantity of water; for the production of especially delicate negatives the quantity of carbonate of potash should be reduced by one half. In case of over-exposure, start developing with a fresh weak solution, to which a few drops of a solution of bromide of potassium have been added; or better still, develop with a solution that has already been used. To develop bromide prints, the developer should be diluted with five parts of water.

(2) Separate Solutions:

(a) Sulphite of soda (crystals)	4	parts.
Water	60	"

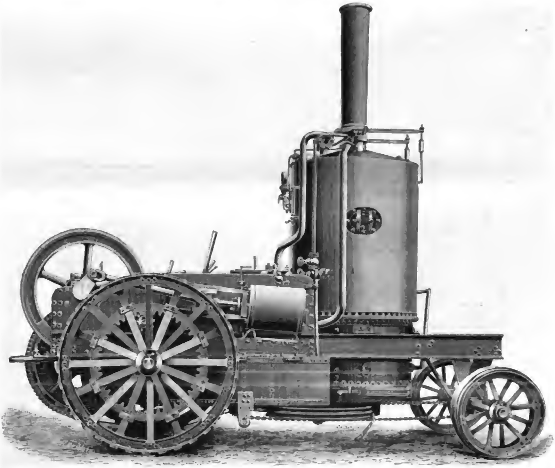
To this add one part of eikonogen, and shake till dissolved.

(b) Carbonate of soda (crystals)	8	parts.
Water	20	"

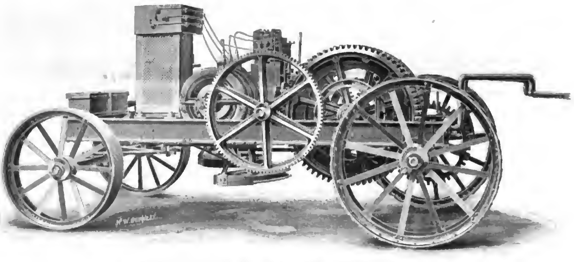
For use, mix three parts of (a) with one part of (b).

Fixing Bath.—Plates which have been developed with eikonogen should be well washed, and can be advantageously fixed in an acidulated fixing bath. To obtain this, dissolve one part of fixing salt in eight parts of water or dissolve five parts of sulphite of soda (crystals) in one hundred parts of water, acidulate with one part of concentrated sulphuric acid, and then add twenty parts of hyposulphite of soda. The bath remains clear even after frequent usage, it hardens the gelatine, and yields negatives of a very fine printing color.

ELECTRICALLY DRIVEN PLOWING TACKLE.



STEAM TRACTION ENGINE FOR PLOWING.



ELECTRICALLY DRIVEN MOTOR FOR AGRICULTURAL USE.

FROM time to time during the last ten years and more we have heard rumors of steam and horses being supplanted in plowing by electricity, but the affairs have usually been only experimental and have led to no permanent results. Lately, however, the system has been worked out in Germany on a commercial basis, and we are now able to lay before our readers illustrations of machines constructed by Mr. A. Borsig, of Berlin, and now being used in many localities. Electric plowing tackle is best adapted to meet the requirement of the great beetroot estates in Germany, which are devoted to the manufacture of sugar, for they are of large extent, and have command of capital to enable them to adopt all labor saving appliances. Further, there are, on such estates, large installations of steam power, which lie idle a great part of the year, including the period at which plowing is done. Hence, by the addition of dynamos, and of a system of overhead conductors in the fields, it is possible, at small cost, to adopt electric plowing over a large area.

The overhead conductors do not extend into all the fields, but are tapped by temporary wires laid on the ground, as required.

In cases in which electric power is not available, Mr. Borsig plows by steam, employing an engine of the form shown in the engraving. It will be seen that it is fitted with a vertical boiler, the firebox of which is furnished with a number of diagonal tubes to increase the heating surface. The boiler barrel can be removed bodily when it is desired to scale the firebox. The engine is self-propelling, and can be used to haul the other appliances to and from the fields. Its arrangement of rope drums is similar to that of the motor wagon we are about to describe.

The motor wagon carries two drums on horizontal axes. On these the two ends of the rope are wound, the bight passing round the sheave on the anchor wagon. One drum is driven to draw in the rope, while the other runs under a brake, to keep the tail rope fairly taut. The two parts of the rope are led round guiding sheaves, revolving in horizontal planes, under the wagon. The two rear wheels can be connected to the motor by clutches and gearing to propel the wagon, while the two leading wheels serve to steer it. On the opposite side of the wagon to that shown in the view there is a platform for the attendant, with the various handles and levers grouped in front of it. The weight of a motor wagon is 7 tons.

Mr. Borsig states that with fixed steam engines of 250 horse power, and with five plows, 6000 acres of medium heavy ground can be plowed to a depth of 14 in. at a cost of 3s. 10d. per acre. If separate engines have to be employed, the cost per acre is increased by 7d. per acre.

The anchor wagon shown in the other cuts carries a sheave round which the plowing rope runs. The sheave is fixed in a guide, and is connected by a chain to the anchor. Hence as the anchor sinks into the earth under the pull of the rope, the sheave and it move together. The anchor itself has four prongs, and is hung from a light crane, or derrick, by which it can be completely raised for traveling, if the jib be wound up by the worm hoist at the opposite side of the frame. At other times it is manipulated by the chains running round the pulleys at the head of the jib. The slack end of the plowing rope, when the plow is moving toward the motor wagon, actuates gearing which winds the anchor out of the ground and moves the anchor wagon forward into the right position for the next double set of furrows. At the same time the anchor and sheave are moved backward relatively to the frame to allow for the slip of the anchor in the earth. The anchor is then dropped by the attendant and the next set of furrows cut. The strain of the rope goes direct from the pulley to the anchor, and not through the wagon frame. We are indebted to London Engineering for the cuts and description.

BLEACHING WAX AND STEARINE.

By S. RAMBOK.

IN bleaching beeswax it is usual to expose the crude material in the form of rather thin, round cakes to the action of the sun, and this way the wax does not lose or hardly lose any of the specific aroma which is one of its much sought for qualities. (Chem. Zeit.) As to the consistency and hardness of wax thus bleached, it is equal to that of the raw material. Unhappily, this process has several faults. The chief of these is the long time which the operation takes, and this is a matter which affects the economy of the process to a large extent. Attempts have been made to abridge the time exacted by bleaching operations, but, unhappily, results have not responded to the hopes of the inventors of the methods proposed.

The process which has furnished so far the best results is that which consists in augmenting artificially the richness of the air in ozone. Practice shows us, in fact, that the bleaching rooms for wax situated in the country in the proximity of pine forests operate with much more efficacy than those which are by their situation placed in atmosphere less saturated with ozone. The artificial distribution of ozone is done by finely spraying spirits of turpentine or just lately by galvanic measures. Unfortunately, an effective abbreviation of the period of bleaching is only obtained in this manner when the wax has been melted to begin with in the presence of a certain quality of humidity. If this condition is not filled, the ozone produced, whatever may be the quality of it, has no action on the wax. The proposed is to look for some method of modifying to the best advantage the natural process of bleaching. Having arrived at this conclusion, the author has undertaken a series of experiments on the best manner of carrying the natural method out, and has arrived at the following conclusions:

1. The Proportion of Water in Wax.—Wax entirely dry exacts double the length of time for its bleaching as that which contains from 2 to 5 per cent. of water. If, therefore, an energetic ventilation is arranged, by means of which it is possible to pass moist air over the cakes of wax, a slight humidity will help the operation very greatly, especially if the cakes are not too thick.

2. Saturation with Humid Air.—When the air is saturated by steam vapor, four times as much time is required to arrive at an identical result, even when the other conditions are most favorable.

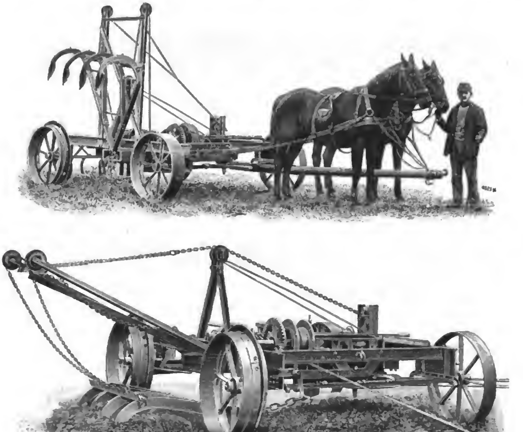
3. Surface Exposed.—All other conditions being equal, the time of bleaching is in direct relation with the amount of surface exposed. It is, therefore, of the highest importance to expose to the action of the air and sun as much surface as possible.

4. Temperatures.—If the wax containing 3 per cent. of water and in slices as thin as possible is exposed in a refrigerator at a little under freezing point to the direct rays of the sun, no traces of bleaching are noticed for a long time. If, on the other hand, the wax is exposed to the direct sunlight at a temperature of about 75 F., bleaching takes place very rapidly (about 70° F. is sufficient for the commercial operation).

5. The Sun.—As we have seen in the preceding paragraph, the action of light is almost nil at low temperatures. According to the personal experience of the author, diffused daylight seems to have rather more energetic action than that of the direct rays of the sun, all other conditions of temperature, air, etc., being equal.

A bleach of surprising rapidity is got with the Laval "Emulsor." If the virgin wax is melted and made into an emulsion with water at from 75° to 100° C., and if after stopping the emulsionizing apparatus the mass obtained is thrown into cold water, the result is to get a quantity of globules of wax of extreme tenuity, which in favorable weather are bleached at the end of two or three days. If the wax is melted, to begin with, with a third of its weight of wax already bleached, the operation does not take more than forty-eight hours. As the apparatus gives a considerable yield (220 gallons of emulsion per hour), the process may be considered as a very practicable one from a commercial point of view. With the aid of this apparatus, which is capable of giving the matter to be bleached a very extended surface, we believe that natural bleaching can enter into serious competition with the chemical bleaching, at least so far as the saving of time is concerned. And if, on the other hand, the fact that the natural properties of the wax are preserved by natural bleaching is taken into account, we do not doubt that this new process will be universally adopted. The high prices actually obtainable, and the more and more frequent adulterations of the product, will give an extraordinary value to a process which will leave the wax the natural and characteristic signs of purity.

With the same emulsionizing apparatus the chemical bleaching can be done in ten minutes as follows: The crude material is emulsionized in slightly alkaline water and brought up to 175° F., then after having been treated with hypochlorite of sodium and



THE ANCHOR WAGONS, SHOWING ANCHORS RAISED AND LOWERED.

production of the ozone by turpentine is alway perfect, for the simple reason that the peculiar aroma of the wax is better preserved in this way.

But although the period of bleaching seems to be sensibly shortened by the aid of ozone, nevertheless entire weeks are needed, and if the weather is unfavorable even entire months, to bleach the wax in satisfactory fashion. A number of processes of bleaching by the aid of drugs have been tried and practiced industrially with the object of arriving more rapidly at the end proposed, but unhappily none of them is capable of destroying the coloring matter alone without harming some of the other properties of the material. At the same time that color disappears the chemical products employed destroy the special aroma of the wax, which, of course, is very similar to that of honey. Moreover, methods of energetic oxidation have influence on the consistency of the wax, which they render brittle. Therefore, although bleaching by chemical means hardly needs more than twenty-four hours, and gives an absolutely white product, the process has not been generalized. In the few factories where it is adopted, from 5 to 10 per cent. of matter naturally colored and aromatized is added to the bleached wax to recover as nearly as possible the tone and the perfume of the original product. Still the product thus treated changes color and loses its perfume at the end of a few days. The essence of wax prepared by Schimmel & Co. has also been tried, but the results have not given satisfaction. The product aromatized by its means loses its perfume rapidly, and ends by giving out a disagreeable odor of gasoline. It follows, therefore, from what we have said, that the only way of reaching the end

If we put these observations into practice, a white wax with the odor of honey will be obtained in a relatively short time. This aroma will not disappear after years of storing if the product is storked in closed vessels and kept in an obscure place. In addition to the greater surface to be given to the matter to be bleached, great care should be taken not to work except in ventilated rooms provided with heating apparatus which can be regulated at will, so as to give the needed heat to the air in humid and cold weather.

If the wax which has been bleached is melted with virgin wax, the bleaching of this latter seems to take place more rapidly; thus, for example, if two pounds of crude wax are melted with one pound of bleached material, only half the time will be needed to bleach this mixture that would be taken in bleaching three pounds of crude wax. We can say, therefore, that the bleached material bears in itself the power of bleaching, and this fact is in direct parallel with the other fact already noted, that a very considerable time is needed before the action of bleaching begins to show itself on the surface of the raw material, and that, on the other hand, as soon as the surface begins to show the bleach, the effect produced transmits itself very rapidly through the whole of the mass.

If the wax is melted and poured on thin plates of iron and exposed thus to the bleaching agents, this also contributes to accelerate the action of bleaching.

allowed to rest for ten minutes, hydrochloric acid is added until an acid reaction is obtained. The mass is then emulsionized anew in warm water to get rid of the acid which adheres to the particles, and a white wax is then obtained with very fine grain and free from ash. Its only fault is that it lacks aroma. The same satisfactory results are got with Japan and Carnauba waxes.

Finally, we may note that the fatty acids for stearine making, whether got by distillation or expression, behave like animal wax in the presence of bleaching agents, and it is also possible to accelerate the bleaching of these products in the same way. The well known and frequent difficulties of manufacture, when the candles remain for entire weeks without changing in the bleaching room, without a plausible reason for the phenomenon being apparent, arise without doubt from the insufficient state of hydration of the stearine, or from a too low temperature, or from the surrounding air giving off too much humidity. If, therefore, stearine already bleached is melted with crude stearine and emulsionized in lukewarm water, so that the mixture can be thrown into cold water with or without the addition of a little oil of turpentine, a very white and beautiful stearine will be obtained in a few days even under bad conditions of climate. The stearine becomes very hygrometric by emulsion. The fusion eliminates the water, and it is only a very small proportion that the stearine retains in purely mechanical mixture. From this moment the bleaching takes place very rapidly. The candles moulded out of the stearine dry thoroughly during the bleaching and burn in a normal manner.—Pharmaceutical Era.

ON CHICLE GUM.

By Edward N. Butt.

When at Campeche, in Southern Mexico, a few weeks ago, in addition to logwood, mahogany, hides and other miscellaneous cargo, we shipped from thirty to thirty-five tons of chicle gum. At Progreso, in Yucatan, our next port of call, another twenty-five tons of chicle gum was added to the cargo. From subsequent inquiries I found that the gum in question was produced by the Achras sapota, a tree which grows wild in the forests in the state of Yucatan and the immediately adjoining states of Central America. It is indigenous from Mexico to Guiana, and cultivated in all tropical countries.

In the states of Campeche and Yucatan the Peons, as the lower class of natives of Aztec descent are called, search the forests where these trees grow, and, having selected those which are sufficiently mature, make V-shaped incisions in the stem. The juice which exudes from the incision soon becomes indurated by exposure to the scorching heat of the sun and is subsequently collected. Fresh V-shaped incisions are made in the same trees from time to time for a period of two or three years and the indurated gum collected. The trees are then allowed to rest for four or five years, after which period they are again fit to undergo the tapping process and yield fresh supplies of gum. When a sufficient quantity of the crude gum has been collected it is pressed into thick oblong blocks, which weigh from twenty-five to thirty kilos each. The collector then usually carries the gum to the stores of the merchants, either suspended from his head or packed on burros, as the Mexicans call that patient animal the donkey. The exporting merchant usually packs three of these blocks in a bale, the average weight of each bale being eighty kilos. In the year 1895 no less than four million pounds weight of chicle gum, of the estimated value of one and a half million dollars gold, was imported into New York from Mexico. I inquired for what purposes this large quantity of gum was used, and found it was the basis or chief ingredient used in the manufacture of "chewing gum," a substance practically unknown in this country, but almost universally used in the United States by men, women and the young of both sexes, many of the male population having adopted it as a harmless substitute for tobacco. The habit of chewing "chewing gum" is said not only to increase the flow of saliva, but to relieve indigestion and dyspepsia. This may possibly be the case with those samples which contain pepsin, especially as the once prevalent habit of spitting is rapidly on the decline, partly due to the substitution of gum for tobacco for chewing purposes, but mainly in consequence of the affixing of notices in all the street cars of most of the cities in the Eastern States prohibiting spitting therein, signed "By order of the Board of Health."

When I had obtained the above information respecting chicle gum, I determined to make further inquiries and obtain as much information as I could about the manufacture of "chewing gum" during the short time I was in New York.

A quarter of a century ago there were practically only two kinds of "chewing gum" in use in the United State, viz., the regularly prepared spruce gum and shoemaker's wax. A little later a mixture of paraffin wax with either resin, balsam of tolu or some other ingredient of a similar character was put on the market. This new variety of chewing gum rapidly became a favorite with the ladies and also with the youngsters, who called it "Coal oil gum." Preparations called "Taffy tolu" and "Snapping wax" were next introduced for similar use. These preparations acted as the pioneers for the enormous trade which has sprung up in "chicle chewing gum." Its present use was discovered by an accident. Some twelve or fourteen years ago a lot of this Mexican gum was sent to New York on board ship partly as ballast and partly in the hope that it would be found suitable for use by bookbinders or possibly in the leather trade. After several trials it was found to be quite useless for any known purpose, and failing to find a purchaser, it was decided to tow it out to sea and throw it overboard in order to get rid of it. Just at that time one man out of the hundreds who were standing at the wharf casually picked up a piece of the gum, examined it and found it would "chew." The idea at once occurred to him that it would form a suitable basis for making a new kind of chewing gum, and without difficulty he succeeded in obtaining the whole lot for the trouble of shoveling it out of the ship. That man was a Mr. Adams, the head of the firm of Messrs. Adams, Sons & Company.

Mr. Adams' first venture in making chewing gum was cooked in a tea kettle and worked up on the kitchen table. Now, the gum as taken from the bales is first chopped into small pieces and then boiled in water. Wood, pieces of bark and all other impurities which are light separate from the gum, float on the surface and are skimmed off, while those which are heavy, such as dirt, stones, etc., fall to the bottom. When the gum is perfectly clean and all the foreign substances have been got rid of, it is removed to a mill where it is ground up, the mill making about three thousand five hundred revolutions a minute. The ground gum is then subjected to a continuous heat of 110° F. in drying rooms. When the gum is sufficiently dry, it is sent to the cooks, who put it into large steam jacketed pans and add to it pure white sugar, granulated pepsin, powdered kola or other desired ingredients. It is then turned and mixed by an ingenious double acting rotating paddle until it has assumed the consistency of bread dough. The "dough boys" then take it in hand and add to it the flavoring ingredients, such as oil of peppermint, oil of wintergreen, etc., and while still warm thoroughly work and knead it until it looks like gingerbread, finely powdered sugar being added from time to time during the kneading process to prevent its sticking. It is then allowed to cool and afterward passed through steel rollers until reduced to the proper thickness, when it is removed to the markers, steel-knived rollers which partly cut through the long sheets of gum. Next it is removed to the seasoning room, and finally broken up into pieces of suitable size on the lines left by the markers. The finished gum then goes to the wrapping room, where the nimble fingers of one hundred and fifty to two hundred young ladies wrap it in waxed paper, tinfoil and pretty wrappers, and thence to the packers, who pack it in jars or boxes ready for sale to the numerous dealers.

RECIPES FOR MAKING CHEWING GUM.

Should any one in this country be desirous of embarking in the manufacture of this article, I append a few formulæ which I have taken from Merck's Market Report, but the different varieties and various flavors now on the market may be numbered by hundreds. Those varieties, however, of which chicle gum is the basis, are those which are most in favor at the present time in the United States:

1. Balsam tolu	4	parts.
Benzoin	1	"
White wax	1	"
Paraffin	1	"
Powdered sugar	1	"

Melt together, mix well and roll into sticks of the usual dimensions.

2. Balsam tolu	4	parts.
Resin, white	10	"
Paraffin	3	"
Powdered sugar	Sufficient.	

Melt the balsam, resin and paraffin together, and, while still fluid, incorporate sufficient sugar to make a suitable mass. Roll out with powdered sugar and cut into pieces.

3. Balsam tolu	3	parts.
Powdered sugar	1	"
Oatmeal	3	"

Soften the gum on a water bath and mix the ingredients; then roll in powdered sugar and cut into sticks.

4. Venice turpentine	40	parts.
Common turpentine	80	"
Yellow wax	20	"
Balsam tolu	4	"
Balsam Peru	2	"

Melt together and add in fine powder—

Cinnamon	12	parts.
Chocolate	30	"
Red sandalwood	4	"
Sugar	2	"
Myrrh	2	"
Galangal	2	"
Ginger	2	"
Cardamom	1	"

Mix, and, when sufficiently cool, roll out into sticks or any other desirable form.

5. Gum chicle	3½	pounds.
Paraffin wax	1	"
Balsam tolu	2	ounces.
Balsam Peru	1	"

Dissolve the gum in as much hot water as it will take up, melt the paraffin and mix all together, then take—

Sugar	10	pounds.
Glucose	4	"
Water	3	pints.

Dissolve the sugar and glucose in the water, boil the solution up to the "crack" degree, pour the sirup upon an oil slab, turn into it sufficient of the above gum mixture to make it tough and plastic, incorporate the flavor (powdered cinnamon, chocolate, sandalwood, myrrh, ginger or cardamom), and when sufficiently cool roll into sheets or sticks.

As there is "so much money" in chewing gum, some one may be desirous of going into the trade, but before starting to manufacture he must make sure of a continuous supply of the raw material. At the present time the whole of the export trade in gum from Mexico is in the hands of a very few persons, and the importers and manufacturers in the United States are also very few in number, less than half a dozen, I believe, who not only hold contracts with the exporters, but also refuse to sell the raw material.—Pharmaceutical Journal.

WORLD'S TEXTILE PRODUCTION.

In Kuhlow's, published at Berlin, we find the following:

"The production of raw material for the manufacture of textile fabrics has increased very much during the past forty years.

"In 1850 the quantity of wool grown in Europe, the United States, La Plata, the Cape and Australia amounted to 805,000,000 pounds; in 1870 to 1,371,000,000 pounds; in 1880 to 1,577,000,000 pounds; and in 1895, according to the 'Annual Report of the President of Permanent Commission on Customs Valuation,' to 2,334,000,000 pounds, or nearly three times as much as that available for manufacture in 1850, 70 per cent. more than in 1870, and 45 per cent. more than in 1880.

"The increase in the quantity of cotton available for commerce, and which increase goes on from year to year, has also been marked. It is estimated that the amount yielded by the United States, India, Egypt and other countries was 695,000,000 pounds in 1830, 1,192,000,000 in 1840, 2,391,000,000 in 1860, and 4,000,000,000 in 1880. According to the report of the president of the valuation commission, the world's cotton crop in 1895 was 18,200,000 bales of 400 pounds, or about 7,280,000,000 pounds. This is eleven times more than in 1830, six times more than in 1840, three times more than in 1860, and 80 per cent. more than in 1880. The above mentioned report states 'the consumption cannot keep pace with the production,' but if the retail price should fall, many consumers would become large purchasers. The report adds that 'spinners never had such an opportunity of stocking at a low price, but that the year was less advantageous to the weavers than to the spinners.' Of the 18,200,000 bales produced in 1895, 10,500,000 bales (those of 450 pounds) were from the United States, 2,600,000 bales (of 400 pounds) from India, and 634,000 bales (of 717 pounds, or nearly two ordinary bales) from Egypt. In the United States alone the area of land cultivated with cotton amounts to upward of 20,000,000 acres.

"The report of the valuation commission deals, in the third place, with silk. In 1895 the quantity of raw silk produced and put on the market was 35,000,000 pounds; in 1894, 30,250,000 pounds; and in 1893, 33,000,000 pounds. Europe and Asia Minor supplied from 35 to 38 per cent. of the whole, the far East from 64 to 65 per cent., but China is still the chief exporting nation for this raw material, having sent out in 1895 13,500,000 pounds. Japan is progressing rapidly; she produces already as much silk as all the European countries together, and is continually increasing her mulberry plantations. Although the yield increased in 1895, there was also a very evident rise in prices. For some time silk manufacturers have been making great progress in the United States, and the establishments of that country, according to the report, are in the first rank as regards the amount of silk worked up, viz., 9,372,0.0 pounds, as against 8,008,000 pounds in France, 5,610,000 pounds in Germany, 3,652,000 pounds in Switzerland, and 5,610,000 pounds in Russia.

"With regard to flax, hemp and other materials, the report does not state the amount of production at the disposal of the industries of the world, owing doubtless to the difficulty of obtaining information on this point. The production of flax in France has not ceased to decline, in spite of the very high bounties granted, and the area of land cultivated with flax in that country does not exceed 89,000 acres."

CAN THE HAIR TURN WHITE FROM FRIGHT?

The man whose hair has "turned white in a single night" from fear or under strong emotion used to figure extensively in stories and popular tradition. The possibility of his existence has been denied by some, but cases of the kind are too well authenticated to be thrown aside. A contributor to Cosmos (Paris, February 27) details some recent investigations that have been made on the subject, and gives us a physiological explanation of the process, says the Literary Digest.

"Toward the age of forty years, sometimes a little earlier, the hair begins to turn gray. This grayness appears at first in the region of the temples, where threads of silver mingle with the hairs and their number increases day by day; the head turns gray and then whitens. It is a phenomenon of vital regression, common to mammals, and to many animal species. Brown-Sequard has studied its mechanism. The hair turns gray progressively and slowly, but the isolated whitening of a single hair is generally rapid and may take place in one night. This observation of the celebrated physiologist gives some credit to the stories of rapid and even sudden whitening of the hair, told by divers authors. If normally a single hair can whiten in a few hours, it is not difficult to explain that in certain determinate cases the thing can take place with a lock of hair, or even the whole head.

"M. Fere has cited an instance of this in Le Progrès medical (January 23, 1897) and has referred us to the facts published in his well known work on 'The Pathology of the Emotions' (Paris, 1892).

"His memoir has given several authors the opportunity to recall their own observations on the subject, and we shall cite a few cases that seem to bear the stamp of authenticity.

"Dr. Parry, in the Dublin Medical Press, May 8, 1861, gives the following instance:

"'On February 19, 1859, the command of General Franks, operating in the southern part of the kingdom of Oude, had an engagement near the village of Chamba with a body of rebels; several of the enemy were taken prisoners; one of them, a Sepoy of the Bengal army, aged about fifty-four years, was led before the authorities to be questioned. I then had occasion, says Parry, to observe in this man, at the very moment when they took place, the events that I propose to relate:

"'The prisoner seemed for the first time to be conscious of his danger when, deprived of his uniform and completely nude, he saw himself surrounded by soldiers. He then began to tremble violently, terror and despair were depicted on his face, and, though he responded to the questions addressed to him, he seemed actually stupefied by fear. Then, under our very eyes and in the space of scarcely a half hour, his hair, which we had seen was a brilliant black, turned gray uniformly over his whole head. A sergeant who had made him prisoner cried out, "He is turning gray," and so called our attention to this singular phenomenon, which we, as well as many others, were then able to follow in all its phases. The discoloration of the hair took place gradually, but it became complete and general in the short space of time already mentioned.'

"With this so precise observation we may compare the assertion of Bichat, who saw one of his friends grow quite white in the space of a single night, after having experienced a violent emotion.

"The unfortunate Queen Marie Antoinette grew almost entirely gray during the night preceding her execution.

"Moleschott relates that Louis Sforza grew entirely white in the night following his defeat and capture, after his campaign against Louis XII.

"A Dutch physician, Junius, tells of a nobleman of high rank who, being condemned to be beheaded, grew gray in one night.

"The same thing happened to the Seigneur de St. Vallier, father of Diana of Poitiers, while Guarini, professor of Greek at Verona, grew gray all at once on learning of the loss at sea of a chest of manuscripts that was coming from Constantinople.

"Thompson cites the case of a workman at York, who, having fallen from a high building that he was repairing, succeeded in holding on to the gutter with one hand. He was rescued, but not until his hair had turned white

"The cases in which the change of color is not instantaneous, but is very rapid, appear to be most frequent. Bichat relates several. . . .

"Emotional grayness seems to be favored by pressure; when after the shock the subject remains during some time with his head resting on his hand or his arm, the compressed part is often the only one affected, or at least is particularly affected. A case of this kind was related several years ago to M. Fere by one of his patients whose father was a physician. . . . Young O——, then aged five years, was in a carriage with his mother when the horse ran away. He was greatly frightened, but suffered no physical injury. Two days afterward he had an eruption all over his body, without fever; . . . eight days after the accident it was seen that the child had, on the hair of the right side of his head, five white spots, whose position and form corresponded to

the prints of five fingers, and the mother remembered that she had held her hand on the head of her child in this position in endeavoring to protect him. The change of color of the hair was permanent, the spots even increased in size; at present (ten years later) the largest, which is the nearest to the forehead and corresponds to the position of the thumb, has nearly the size of a two franc piece."

After citing several more curious and well authenticated cases of the kind, including some in which grayness was brought on by an apoplectic stroke, the author concludes as follows:

"This grayness following an apoplectic stroke is analogous to the cases that have an emotional cause. These last are not absolutely unheard of among animals. Thus Thompson tells, according to Young, of a blackbird which had been surprised in its cage by a cat, and which, when it was rescued, was found lying on its back and covered with sweat; its feathers fell off and grew in perfectly white. A gray linnet was once seized in its cage by a drunken man who tore its feathers off, the little creature lived, but its feathers grew in again white.

"When the hair whitens, the phenomena that takes place are easily understood, and they have been made a special study by Pincus. The quantity of air contained normally in the hair cavity increases, and at the same time there disappears or diminishes a pigmented oil that is secreted by the hair follicles, and that gives to each hair its characteristic color. It is well known what influence the nervous system has on the secretions and, in general, on the sebaceous glands; it would be surprising if those of the hair should escape this influence, and so the sudden whitening of the hair, whose possibility has sometimes been denied, is explained from the physiologist's point of view."—Translated for the Literary Digest.

CARE OF THE EARS.

The ears are not often treated of, even in popular manuals of hygiene, probably because it is not thought that much can be done by the owner of the ears to modify or in any way improve them, says the Independent. You go to an aurist, he takes his watch in hand and proceeds to test your hearing, and he talks about "necessary hearing," "superfluous hearing," "good hearing," "normal hearing," etc., while the patient can hardly be made to believe there can be such a thing as superfluous hearing. A few years ago an eminent aurist tested the hearing of twenty-five patients of an eye and ear hospital, who never had suspected that their hearing was not perfect—only five of them proved to have perfect hearing, i. e., that which could be called normal; but the twenty whose hearing could not come up to the "normal" standard had never imagined that there was any deficiency, and so this class of persons are classified as being possessed of "necessary hearing," and they have all that is needed to enable them to perform the ordinary duties of life.

It is surprising how many of the persons who consult the aurist are relieved by simply having a mechanical obstruction removed; either an accumulation of wax or a wad of cotton that has been put in at some long forgotten time when the patient had an attack of earache. When there is an accumulation of wax it usually follows measles or scarlet fever and is easily removed by dropping a little sweet oil in the ear, allowing it to remain till the wax is softened and then syringing the ear, preferably with a douche from a fountain syringe; but if a person is out of range of this excellent appliance, a very good substitute can be improvised by filling a quart bottle with warm water (as hot as can be borne) and attaching a sufficient length of rubber tubing to its mouth, inverting it and allowing the water to flow through the tubing to the ear. In the case of impacted cotton wads the course of action is generally this: The person takes cold, the membranes of the ear become swollen and sensitive in sympathy with the throat, but the patient has his attention fastened on the ear, and to protect it he inserts the cotton. In a few days the inflamed membranes of his nose and throat become normal, the sensitiveness of the ear is forgotten and the cotton remains; but the man says: "In fact, I've never heard well since I had that terrible cold five years ago." It is simply a mechanical obstruction that he is suffering from.

An experienced aurist raises the note of warning against the use of ear spoons, ear sponges, etc., that are to be found in any druggist's shop. He denounces them as worse than useless—as often the active agents of irreparable harm. He says there is more wisdom than humor in the old adage "Put nothing in your ear but your elbow." The end of the little finger wrapped in a handkerchief is allowable, but nothing else.

The deafness from accumulated wax is generally sudden, and is accompanied by a dull, rumbling sound, and it should at once be carefully looked at and treated by a competent observer.

We have been hearing a great deal lately about "preventable blindness," and it is a matter of devout thankfulness that the thousands of blind infants that have swelled the ranks of the dependent classes will now be saved by the immediate Crede treatment—especially in those States which have enacted laws to punish the ignorant neglect of unintelligent nurses and midwives, who do not realize that while they are pottering with tea leaf dressings a hopeless curtain of opacity is spreading over the cornea, while the proper application of nitrate of silver would arrest the mischief. The attendants at our eye infirmaries say it is most pitiful to see the mothers of children three and four weeks old, who bring the children with cornea gone, and are told that the time to save the sight was before the child was seven days old.

Now as to "preventable deafness"—for the aurist tells you that most of the deafness which robs people of much of their "necessary hearing" is not primarily dependent on the ear at all—the real cause is to be found in a swollen and inflamed condition of mucous membrane that lines the upper portion of the nostrils and the back part of the throat; and of course the point to which efforts to improve the hearing should be directed is the membrane lining the nostrils and throat. The man who tested the defective ears—Dr. A. M. Fanning—deprecates the snuffing up of salt or salt water from the hand as is often done, and recommends instead a solution of common baking soda (bicarbonate of soda) both as a gargle for acute sore throat and as a wash for the interior of the nose itself. He says: "It is a great mistake forcibly to snuff it into the nostrils from the palm of the hand, as is commonly done. . . . The best and simplest way to use the soda solution is to bury the nose entirely in the cup of fluid, and then gently suck the solution into the nose, at the same time holding the mouth widely open. There is no risk of choking if the mouth is open and the head thrown forward, for all the fluid will run out at the mouth. Careful attention to the general health, all judicious measures of exercise, a diet that will insure sound blood—counteracting inflammatory tendencies—and, above all, care to avoid taking cold, is the true 'treatment.'"

TETANUS ANTITOXIN.*

One by one the diseases which have hitherto defied the skill of physicians are yielding to the persistent attack of modern science. Since the successful treatment of diphtheria by subcutaneous injections of antitoxic serum was demonstrated—hardly three years ago—it has been confidently predicted that sooner or later all diseases which result from the action of a poison secreted in the blood by a special and characteristic bacillus would be conquered by similar means.

From the evidence now presented, it would appear that tetanus, one of the most sinister and stubborn of human maladies, if not already conquered, is in a fair way to be successfully overcome. In the Deutsche Medicinische Wochenschrift (Berlin) for October 23 appears a joint announcement by Prof. Dr. Von Behring, of diphtheria antitoxin fame, and Prof. Knorr, of Marburg, describing the qualities and best methods of using the new tetanus antitoxin, which is now prepared under government supervision as a commercial product by the Farbwerke at Hoechst-on-Main, and offered for use by medical practitioners under the same conditions as diphtheria antitoxin from the same source.

Tetanus, as is well known, is an exceedingly painful and hitherto usually fatal disease caused by blood poisoning, generally the result of a wound. It is believed by physicians to be caused by the introduction into the system of a minute organism which rises from the ground in certain localities, so that the prevalence of tetanus varies greatly even in different districts of the same country. At all events, the disease has its characteristic microbe, which has been recognized, isolated, described and reproduced by artificial culture. The distinctive symptom of tetanus is a persistent spasm of the voluntary muscles, aggravated by light, noise or other disturbing influence to which the patient may be subjected. These spasms may affect any muscular portion of the body, but when, as is often the case, the maxillary muscles are principally attacked, the resulting malady is known as lockjaw.

The tetanus antitoxin described by Prof. Behring and Dr. Knorr is similar in nature, action and in the methods of its preparation to the antitoxin of diphtheria. It is prepared and put up for use in two forms, viz., as a dry powder, which is used for the treatment of developed cases of tetanus in men and animals, and as a liquid solution, which is employed for prophylactic purposes. Its strength or degree of efficiency is measured, like that of antidiphtheritic serum, by antitoxic units. The dry antitoxin is designated as a hundredfold normal antitoxin—that is, 1 gramme of the preparation contains 100 units of antitoxic power; in other words, is sufficient to neutralize 100 grammes of the normal poison of tetanus. It is put up for commerce in vials containing 5 grammes each, and the contents of one such vial are theoretically sufficient for the cure of a developed case of tetanus. It is dissolved in 50 cubic centimeters of sterilized water at a temperature of 40° C. and injected hypodermically at a single dose. In the treatment of horses, the injection is made into a vein, by which the full action of the antitoxin is accelerated by about twenty four hours, and this method of injection may even be employed with human patients in very severe cases or where the treatment is commenced at a late and perilous stage of the disease. To insure favorable results, the injection should be made, if possible, within thirty-six hours after the presence of tetanus is definitely indicated. The liquid solution is protected from contamination by germs in the atmosphere by a small admixture of phenol. The dry preparation, on the other hand, requires no such antiseptic while in that form, but when dissolved in water it becomes subject to deterioration, which may be prevented by the addition of one per cent. of chloroform.

The tetanus solution is of fivefold strength, that is, 1 gramme of the liquid contains five antitoxic units, and in this form it is put up in sealed 5 gramme vials. In presence of wounds which give reason to fear lockjaw or other form of tetanus, a small subcutaneous injection of the solution is made, the quantity used being proportionate to the condition of the patient and the time that has elapsed since the injury was received. In all cases the wound should be antiseptically treated, so as to prevent as far as possible the further generation of poison in the blood.

Tetanus is a disease of seldom occurrence in this section of Germany, and opportunities to test the remedy in actual practice are comparatively rare. One such case has been recently treated at the hospital of the Holy Spirit, in Frankfort, the record of which is officially and minutely given.

On September 19 last a coppersmith (L. M.) twenty-five years of age and resident in Frankfort experienced, after exposure to thorough wetting, severe pains and stiffness in the muscles of the neck and throat. Two days after the first symptoms appeared he came under treatment by a physician, who kept the patient in bed and administered chloral and salicylate of soda. The symptoms of tetanus continued to develop, and on the night of September 29 became so marked and violent that on the following day the patient was transferred to the hospital. A careful examination revealed a small cut or scratch under the right ear, then nearly healed, and so slight in outward appearance that it had passed almost unnoticed. At the time of admission to the hospital the patient was growing rapidly worse. The chin was twisted far to the left, the head drawn backward and immovable and the muscles of the body, especially the back and abdomen, were hard and tensely drawn. The patient was isolated in a dark room and treated with subcutaneous injections of morphine, which gave no relief. The slightest noise or disturbance, such as the entrance of the physician or nurse into the darkened room, induced severe spasms, and the condition of the sufferer continued to grow steadily worse. At 4 o'clock in the afternoon of October 1 a prolonged spasm of intense severity left no further doubt of a fully developed case of tetanus, and half an hour later 5 grammes of the hundred unit antitoxin, dissolved in 50 grammes of water, were injected hypodermically at three places on the breast.

During the evening of the same day a slight but definite improvement was observed, and this continued throughout the following day, the spasms being fewer and of shorter duration than before the antitoxin had been administered. This condition was maintained from October 3 to 6, when the acute symptoms gradually returned, and by 9 o'clock in the evening became so severe that a second dose of 4 grammes of normal antitoxin was administered as before, with the result that before the next morning the muscles began to relax, the spasms became lighter and less frequent and from that time improvement was so rapid and sustained that on October 23, sixteen days after the second injection of antitoxin, the patient was convalescent, and, at his own request, was discharged from the hospital.

This, in the opinion of the physicians in charge, was a typical and conclusive case, in which life could not have been saved by any other treatment previously known, and in which the course of the disease might unquestionably have been arrested and greatly shortened had the antitoxin been used when the patient first came under medical treatment, instead of ten days later, when the case had become one of acute and fully developed tetanus.

It is, of course, too soon to estimate the exact prophylactic or therapeutic value of the new remedy. That can only be determined by a long series of observations in actual practice, which will be made as rapidly as the comparative rarity of the disease itself will permit. Thus far the antitoxin has been used experimentally, both in this country and in France, with horses, cattle, guinea pigs, mice, etc., and from these tests and the hospital case above described the indications are that its use entails no injurious result. The antitoxin is prepared with extreme care, subjected to rigid inspection and control at the imperial testing laboratory at Steglitz, and with this guarantee is placed within reach of bacteriologists and medical practitioners in all countries.

FRANK H. MASON,
Frankfort, November 16, 1896. Consul-General.

* U. S. Consular Reports.

THE POISON OF SUNSTROKE.

Dr. Ira Van Giesen, director of the State Pathological Institute, at Madison Avenue and Twenty-third Street, contributes an interesting tentative review of the investigation and experiments into the nature of sunstroke made in this city during the heated term last summer to the State Hospital Bulletin, recently issued. The experiments attracted widespread attention at the time, since they involved the study of sunstroke from the standpoint of physiological chemistry, from which aspect the disease had previously received but little attention from the medical world.

Dr. Van Giesen believes that the investigations have established the auto-toxic nature of the disease. He considers it remarkable that sunstroke has not received more attention from that standpoint, because of the tendency of many authorities to place diseases in the category of auto-intoxications when they have comparatively insecure proofs.

He describes sunstroke as "a brilliant example of an acute, intense, and virulent poison originating within the body, acting rapidly and violently upon the nervous system." He became convinced that the acute degeneration of the cortical cells was due to the action of a poison, and the outbreak of the affection in this city afforded excellent opportunities to substantiate, if possible, that theory. The results obtained from experiments showing the effects of the body fluids and excretions of living cases of sunstroke upon animals are described in detail.

Repeated injections of urine in rabbits from several different cases showed uniform hypotoxicity shortly after the sunstroke occurred. Injection of the cerebro-spinal fluid and ventricular fluids taken from the brain of fatal cases showed lethal results in some animals. These experiments, however, are not considered to have much significance, since the animals died when not under observation, some hours after the injection.

Prompt and decisive results were obtained from injections of blood serum taken from patients during the period of what is known as hyperpyrexia. These experiments were noteworthy and are described at much length. Although Dr. Van Giesen has noted fatal results in some such cases which could not be attributed to the injection of the material, he believes that there "was no mistaking the cause of death which occurred so uniformly in these animals in succession. This result is in consonance with the hypothesis that the rapidly fatal course in severe cases of sunstroke is due to an intense, rapidly acting poison, circulating in the body fluids. If this view be correct, it was to be expected, as was in fact the case, that even the small quantity of blood serum used in the rabbits would produce experimentally this rapid, prompt and fatal effect."

Other experiments involving the injection of urine from convalescing patients into the blood circulation of rabbits were also attended by interesting results. Dr. Van Giesen thinks that "it is not too much to say that the virulence of the auto-toxic poison in some cases of sunstroke is fully as rapid and violent as snake venom, and considerably resembles its action. Cases of sunstroke which entered the hospitals with purple, swollen faces, rapid and very much enfeebled heart action, and profound collapse, with death occurring within one to two hours, are surely examples of the effects of the most violent poisons that we know of. Such a poison seems immediately to act upon the ganglion cells which govern the heart and which manage the vasomotor apparatus. This brings about such a rapid suspension of the most vital functions that the body hardly has a chance, so to speak, to react against or eliminate the poisons."

Switzerland's National Council has voted unanimously to make insurance against accident and sickness compulsory on all citizens.

SPITZBERGEN.

Our readers may have wondered how it is that we are kept so well informed about the proceedings at remote Dane's Island (near Spitzbergen), the starting point of Andree's north polar expedition. But Spitzbergen, however far from civilized domains, is not by any means without all culture.

Within the last twelve months it has been brought into close union with the European continent by the opening of a Norwegian steamship line from Hammerfest to Advent Bay. This latter port lies on the western coast of Spitzbergen, on one of the finest and largest fiords of the island. For some years there has of course been a considerable amount of traveling to and from Spitzbergen, but the opening of the steamer line has given the island a place among the innumerable places accessible by regular service accommodations. Besides, the company has built a hotel, where the travelers may settle down in comfort, or at any rate find shelter at any time. Norway has provided Advent Bay with a post office, so that little far north settlement now stands in direct union with the Continent, both as regards traveling and mail.

Hammerfest lies farthest north of all European towns. In spite of its seclusion from other townships, it has for some time been supplied with electric lighting.

The cause of this early development lies in the peculiar circumstances which place Hammerfest in unusually great need of good lighting; for two months in the year the sun sends not a ray of light on the town.

From Hammerfest then the boats run to Spitzbergen. Hammerfest itself must be reached by boat, not being in connection with any other Norwegian town by rail.

For centuries Spitzbergen has only been accessible to a few explorers, whalers, Arctic hunters, etc., but now it is open to all. The postal connection will no doubt do a great deal toward increasing the number of tourists visiting the island.

The late successes of Nansen in particular are strong motives with many for a journey to the Arctic regions. Spitzbergen is certainly the most appropriate of all northern territories for tourists. With its rich Arctic flora and fauna, and its glittering glaciers, it offers all the charms of a polar journey, while under the existing circumstances it is easily reached. In a little more than two days the traveler is taken from Hammerfest to Advent Bay; here he finds small steamers under the guidance of experienced captains, ready for occasional trips for seal hunting and Arctic sport.

In these seas there was once an abundance of whales, but whalers of all nations, especially Englishmen, Dutchmen, Hanseates, Baskes and Danes, played such havoc among those great sea mammals that at the beginning of this century their pitiless slaughter, begun soon after the discovery of the island in 1596, had exterminated the whales from those waters. Still the island was frequented, even after that, for its elks, bears, and other furred beasts, and mainly by Russians. At present the western and northern shores of Spitzbergen are struck by Norwegian sailors, to secure furs of the polar bear, to hunt the elks, the seals and eiders. These hunters have thrilling tales of adventure to tell, which must be taken with a grain of salt. Still the danger of a forced hibernation in those regions, with provisions calculated for a much shorter period, is by no means to be made light of. Sometimes masses of ice block the retreat from Spitzbergen in autumn, and the men have to wait till spring to return. In most cases no precautions are taken for such emergencies, and the adventurer who escapes with his life can consider himself fortunate. That a hibernation on Spitzbergen with the necessary provisions is not such a very serious matter is clearly shown by the example of the Russian Staratschin, who spent a large portion of his life on the island. At Green Harbor, a part distinguished by its striking beauty of nature, he spent thirty winters on the cape bearing his name, and of those thirty, fifteen in succession. He died there of old age. To the present day the name of this patriarch of Spitzbergen lives among the Arctic seafarers.

If a stay on Spitzbergen in the long polar night, in spite of the beautiful northern light, involves many discomforts, the summer is all the more charming.

In the vales and lowlands the sun's warm rays soon melt away the snow, and vast expanses of moss and lawn covered ground are soon gay with animal life. On the ice along the shore, too, blue and white foxes and other Arctic animals can be seen. Here the passionate hunter can enjoy such hunting as few other spots on the earth can afford. Polar bears are mostly seen in spring in the fiords, but occasionally one is sighted in summer too.

Under such circumstances it is not to be wondered at that the train of tourists to the island is steadily increasing, particularly now that the traveling accommodation and mail connection to Spitzbergen have received the great improvement which we mentioned at the beginning of our article.

It may be interesting to our readers to hear that the boat which takes you from Hammerfest to Spitzbergen is under command of Otto Sverdrup, the man who has become famous for his successful navigation of the Fram, the ship that bore Nansen and his company on their Arctic expedition.

HOTEL AND POST OFFICE, ADVENT BAY, SPITZBERGEN.

This information about the little island in the distant northern seas will, we hope, be welcome to our readers at a time when the newspapers have just announced the departure of Andree on his aerial journey poleward.

Our illustrations, which show several spots of special interest and beauty on Spitzbergen, are taken from Ueber Land und Meer.

BEES AS WEAPONS OF WAR.

History records two instances, according to Mr Whiteley Stokes in the London Athenæum, in which bees have been used in warfare as weapons against besieging forces. The first is related by Appian, of the siege of Themiscyra in Pontus, by Lucullus in his war against Mithridates. Turrets were brought up, mounds

CAPE THORDSEN, SPITZBERGEN.

were built, and huge mines were made by the Romans. The people of Thennseyra dug open these mines from above, and through the holes cast down upon the workmen bears and other wild animals, and hives or swarms of bees. The second instance is recorded in an Irish manuscript in the Bibliothèque Royale, at Brussels, and tells how the Danes and Norwegians attacked Chester, which was defended by the Saxons and some Gallic auxiliaries. The Danes were worsted by a stratagem; but the Norwegians, sheltered by hurdles, tried to pierce the walls of the town—when, "what the Saxons and the Gaedhil who were among them did was to throw down large rocks, by which they broke down the hurdles over their heads. What the others did to check this was to place large posts under the hurdles. What the Saxons did next was to put all the beer and water of the town into the caldrons of the town, to boil them and spill them down upon those who were under the hurdles, so that their skins were peeled off. The remedy which the Lochlans applied to this was to place hides outside on the hurdles. What the Saxons did next was to throw down all the beehives in the town upon the besiegers, which prevented them from moving their hands or legs from the number of bees which stung them. They afterward desisted and left the city."

New Hampshire, in 1770. There is little evidence of its again occurring in New England in great abundance until 1861, when it was very destructive, as it was also in 1875. The last serious and widespread outbreak in New England appears to have been that of 1880. The army worm is generally destructive in seasons following years of unusual drouth. It is seldom injurious in a given locality for two successive summers, but it is worth while to burn over—in autumn, winter, or spring—fields where it may be present.

The story of the life of the individual army worm may be briefly told. On some summer night there appears in the meadow a good sized light brown moth. Flying about, she finds a cluster of strong growing grass. Into the folded leaves of one or more of these she pushes a number of small whitish eggs, gluing them in rows of a dozen or more. A week or ten days later each egg hatches into a minute, whitish worm, that nibbles at the grass blades at night and in the daytime hides beneath the grass from the rays of the sweltering sun. It grows rapidly in size. At the end of a week it moults or casts its skin, a process in which the old skin splits open along the back, and the worm crawls out, clothed in a new skin that had developed beneath the old one. Again it feeds as before, its voracity increasing with its size. This moulting is repeated four or five times during the month after the worms hatch, so that by the end of this period the insect is an inch and a half long, and has the familiar markings of the full grown army worm.

The instinct of the worm now teaches it to seek more secure shelter for the helpless stage upon which it is about to enter. It burrows into the soil an inch or less and wriggles about in the earth until it produces a hollow cell. In this it casts its skin again and becomes a pupa—the third stage of its existence. When the worms are very abundant, many of them do not go into the ground, but change to pupæ beneath whatever shelter may be at hand. About a fortnight later, another change takes place, and the fully developed moth emerges from the pupa, thus completing the round of the insect's life. The moths fly toward dusk and at night, and by means of their long tongues, coiled up when not in use, they suck the nectar of various flowers. The moths sometimes seem attracted by buildings. I have been told of their swarming toward the close of cloudy afternoons about barns and outbuildings; and early in August, this year, they were trapped by thousands in the projecting porch of Thompson Hall. We killed one thousand of these moths, placed them in a little heap, and photographed them. The photograph is reproduced in Fig. 1. It represents the moths about one-half natural size, and seems a small pile, but had the moths not been killed there might have developed from them in September nearly half a million army worms.

During ordinary years the army worm is present in most of the regions where its outbreaks occur, individual worms feeding here and there in meadows and pasture lands, but the number is not sufficient to attract notice. At such times their habits of life are very similar to those of the common cutworms, to which, indeed, the army worms are closely related. It is only when these insects become so excessively numerous that they exhaust the food supply of the field in which they develop that the "army" habit is assumed. Then, however, they are forced to seek new quarters for food, and as their only mode of progress is by crawling along the ground, they move in solid masses toward adjacent fields. "Their numbers at these times," wrote Dr. C. V. Riley, "are often so enormous, and their voracity so great, that it is impossible for one who has not been an eye witness to appreciate it fully. . . . The army worm when traveling will scarcely turn aside for anything but water, and even shallow watercourses will not always check its progress, for the advance columns will often continue to rush headlong into the water until they have sufficiently choked it up with their dead and dying bodies to enable the rear guard to cross safely over. I have noticed that after crossing a bare field or bare road where they are subjected to the sun's rays, they would congregate in immense numbers under the first shade they reached. In one instance I recollect their collecting and covering the ground five or six deep all along the shady side of a fence for about a mile, while scarcely one was seen to cross on the sunny side of the same fence."

The army worm feeds by preference upon plants of the great grass family, which includes both the grasses and grains. The moths are especially attracted, for the deposit of their eggs, to rank growths of grasslike plants. To this is due the fact that in New Hampshire this year the brood of worms destructive in July was oftenest found in barley fields, while that destructive in September ravaged the fields of Hungarian grass. In feeding upon timothy and similar grasses the leaves are first stripped, and in cases of severe attacks the heads will be wholly or partially gnawed off; one such is represented in Fig. 7. They also feed freely upon the leaves and more or less upon the succulent stalks of wheat, oats, barley, rye, sorghum, and Indian corn. Generally they feed upon clover only when driven to it by hunger.

Apparently there were three broods of worms in New

THE ARMY WORM—VARIOUS STAGES OF ITS DEVELOPMENT.

THE ARMY WORM.

By CLARENCE M. WEED, New Hampshire College Agricultural Experiment Station, September, 1896.

EARLY in July complaints began to reach the Experiment Station of the injuries inflicted by the army worm* upon grain and grass fields. Whenever specimens were submitted, they proved to be the true army worm. Serious injury, especially in barley fields, was done during July; and again in September, when another brood of worms had developed, especial damage was reported to be done in fields of Hungarian grass. As soon as the first outbreak was reported, I visited the infested fields, studying the worms at work, and bringing specimens to the station, where they were placed in breeding cages to determine their life histories. The results of these and subsequent studies, as well as a summary of our knowledge of the insect in general, are embodied in this bulletin.

The army worm is believed to have occurred in New England as long ago as 1743, a year when, according to early records, there appeared "millions of devouring worms in armies, threatening to cut off every green thing." The pest was also present in great numbers in New Hampshire, in 1770. (continued above)

* Leucania unipuncta.

Hampshire this season. Before the destructive brood that appeared in July there must have been a brood developed during late spring or early summer. Some members of this generation, and perhaps most, probably passed the winter as partially grown worms, while others may have wintered over in other stages of the insects' existence, for the broods are by no means definitely limited. In a given field at a given time one may find many sizes of worms. The worms injurious in July were doubtless the second generation for the season. The majority of these entered the pupa state during the middle or latter part of the month and emerged as moths early in August. The progeny of this brood of moths became full grown larvæ in September, changing to pupæ late in the month. It seems almost certain that many of the pupæ must go through the winter without changing to moths; and that many of the moths must hibernate without laying eggs.

The egg of the army worm moth is a tiny whitish sphere with a diameter of only about one-fiftieth of an inch. When first deposited it is dull and opaque, but soon afterward it becomes shiny and more or less irides-

FIG. 7.—Head of Timothy Grass Gnawed by Army Worms. (Original.)

cent. Just before hatching it appears much darker. The spherical outline in many specimens is changed by the sticky material attached to them at the time the eggs are deposited. Specimens, natural size and magnified, are represented in Fig. 4, a, b.

The larva when full grown is of the form represented in Figs. 2 and 4 c. It is a smooth, cutwormlike caterpillar, an inch and a half long, generally of a dark gray or dingy black color, "with three narrow yellowish stripes above and a broader one or slightly darker on each side, thinly clothed with short hairs (to be seen with a lens) which are longer and somewhat thicker on and about the head. The latter is of a polished honey yellow color, with a network of fine dark brown lines and a black line on the front like the letter V reversed." The size of the mature worms varies considerably, some specimens reaching a length of two inches.

The pupa into which the full grown army worm changes before it can become a moth is represented in Fig. 4 d. It is a quiet, footless, wingless object, of a bright mahogany brown color, and measures about three-fourths of an inch in length. At the smaller end

FIG. 8.—Black Ground Beetle. (After Riley.)

there are two pointed projections side by side, and near the base of each projection is a smaller, more slender spine with a hooked tip.

The adult moth into which the army worm develops, and from the eggs of which it originates, is represented, natural size, in Figs. 5 and 4 e. Its expanded wings measure about an inch and a half from tip to tip, although there is considerable variation in the size of different specimens. The general color of the body and front wings is a peculiar reddish gray, perhaps more distinctly described as fawn color. Near the middle of each front wing are two more or less irregular lighter patches, each of which on closer study is seen to be made up of three smaller spots. Along the side margins of both pairs of wings there is a fringe of feathery scales, immediately inside of which, on each of the front wings, is a row of blackish dots. The hind wings are more grayish, with less of the reddish tinge.

Fortunately for the American farmer, the army worm has a host of natural enemies, which generally keep it below the danger line. A large number of birds consider the worms excellent eating, and feed freely upon them. A list of such birds would include nearly all our native insectivorous species that search for food upon the ground, but special mention should be made of the robin, the blackbird, the bobolink and the meadow lark, which search grass lands for insect larvæ more persistently than many other of our common birds. These and other birds are very useful in keeping army worms and cutworms in check, and should be encouraged by every one.

But the birds are not the only enemies of the army worm. In the fields where the pest has been present this season there have also been found a great many large black beetles, some of them similar to the one represented in Fig. 8, and others somewhat larger.

There are also many species of internal parasites that prey upon the army worms. Among the most abundant of these are certain two winged flies that glue eggs upon the backs of the worms. The eggs hatch into tiny footless maggots, that enter the bodies of the worms when they hatch, and develop inside at the expense of their unwilling hosts. Finally they kill the worms and the maggots change to pupæ, from which they soon emerge as flies. These are called tachina flies. There are several species of four winged ichneumon flies that have a similar history, and are often very destructive to the hosts of army worms.

The larger ground spiders also feed freely upon these worms; and the moths are often entrapped in the webs of the spinning spiders (Fig. 6).

To the action of these various natural checks is doubtless due the seemingly strange appearance and disappearance of this vexatious pest. Nature strives ever to keep a balance in her affairs, and when an insect becomes too abundant, she marshals her various forces to bring it into subjection.

When an outbreak of army worms is first noticed, if it is confined to a limited area, it is generally well worth while to cut down the grass or grain infested. The worms will remain beneath its shelter for two or three days, and as soon as the cut grass or grain is dry enough it should be burned, thus destroying the pests and preventing the invasion of neighboring fields. The worms may also be destroyed by spraying them with strong kerosene emulsion. This is prepared by adding 2 gallons of kerosene to 1 gallon of a solution made by dissolving ½ pound of hard soap in 1 gallon of boiling water, and churning the mixture by forcing it back into the same vessel through a forcepump with a rather small nozzle, until the whole forms a creamy mass, which will thicken into a jellylike substance on cooling. The soap solution should be hot when the kerosene is added, but of course must not be near a fire. The emulsion thus made is to be diluted before using against the army worm with five or six parts of water to one part of emulsion. The amount of dilution varies with different insects. Soft water or rain water should be used in diluting. If this cannot be obtained, add a little lye or bicarbonate of soda. It should be applied with a spray pump or nozzle.

The device of stopping the armies of traveling worms by means of ditches and trenches occurred to the earliest sufferers from their depredations. In the New Hampshire outbreak of 1770, Mr. Powers tells us that the inhabitants "dug trenches around their fields a foot and a half deep, hoping this might prove a defense; but they soon filled the ditch, and the millions that were in the rear went over on the backs of their fellows in the trench and took possession of the interdicted food."

Some years ago Dr. C. V. Riley wrote: "From experiments which I have made, I am satisfied that where fence lumber can be easily obtained it may be used to advantage as a substitute for the ditch or trench by being secured on edge and then smeared with kerosene or coal tar (the latter being more particularly useful) along the upper edge. By means of laths and a few nails the boards may be so secured that they will slightly slope away from the field to be protected. Such a barrier will prove effectual where the worms are not too persistent or numerous. When they are excessively abundant, they will need to be watched and occasionally dosed with kerosene to prevent their piling up even with the top of the board and thus bridging the barrier. The lumber is not injured for other purposes subsequently."

One of the simplest ways of preventing injury by the army worm, where it can be done without danger to live stock, is that of dusting or spraying with poison a strip of grass or grain in advance of the invaders. The simplest way of doing this would be to apply Paris green when the dew is on in the morning by means of one of the insecticide bellows now upon the market, designed more especially for use against the potato beetle. We have used two patterns of these this season and found them to do excellent service. One of these, the standard Paris green duster, is shown diagrammatically in Fig. 9. It is an admirable machine, and will distribute a pound of Paris green evenly over an acre of potato vines. The other, called Leggett's insect powder gun, is shown in Fig. 10. It is a slightly larger machine, costing also a little more, but it does excellent work. With either of these machines the poison can be applied much more easily than by any other method.

ON THE RELATIVE VARIATION AND CORRELATION IN CIVILIZED AND UNCIVILIZED RACES.*

THE general conclusion would then be that, with increased civilization, absolute size and variation tend to increase, while correlation, to judge by the males, is stationary; to judge by the females, tends to increase.

It will be found somewhat difficult to reconcile these results with any simple applications of the principle of natural selection. In the first place increased variation undoubtedly suggests a lessening of the struggle for existence, and there can be no question that this increase has gone on among civilized races (see "Variation in Man and Woman"). The lessening of the struggle has probably been greater for woman than man; hence the principle of natural selection might help to explain the preponderance of variability in civilized woman. The increase in size with civilization seems, on the average, also incontestable. But is it the effect of lessening the struggle for existence? The possibilities may, perhaps, be summed up as follows:

(a) The civilized races may have survived owing to their superior size. It may be a result of the struggle in the past. To this must be objected that the increase of size appears to be a progressive change still going on, and yet increase of variation should show a lessening struggle for existence.

(b) The effect of suspending natural selection may be to increase size. This would be a blow for panmixia, for we might naturally have expected a regression to the smallness of the more primitive races. It would leave unexplained the apparently smaller progress of women as compared with men, for in their case we might argue from the variation that the struggle for existence is relatively less than in the case of man.

(c) The larger size of the civilized races may be due to better food supply and better physical training; in short, it may be due, not to evolution, but to better conditions of growth. This hypothesis does not involve the assumption that acquired characters are inherited. Diminish the food supply and abolish physical training, and the size would sink to the level at which natural selection had left it. Physical training in civilized races being usually more adequate in the case of man than of woman would, perhaps, explain why man has progressed more rapidly in size than woman. It seems impossible, taking variation as a measure of the intensity of selection, to reconcile the relative increases in size of man and woman with any direct effect of natural selection.

8. To sum up, then, the following results seem suggested by these measurements:

(i.) Civilized man has progressed generally on primitive man in size, variation and correlation.

(ii.) This progression can hardly be accounted for by increased selection (because of the increased variation), nor by decreased selection (because it is inconsistent with the relative changes in male and female size). It might possibly be accounted for by decreased selection and improved physical conditions.

(iii.) Woman is more variable than man in civilized races.

(iv.) Woman is more highly correlated than man in civilized races.

(v.) In uncivilized races the sexes are more nearly equal in the matter of size, variation and correlation than in the case of civilized races.

(vi.) It is impossible to say that civilized woman is nearer to the primitive type than civilized man, for while civilized man differs more from the primitive type than civilized woman, so far, probably, as abso-

* Conclusion of a communication made to the Royal Society.—Science.

* This is only generally true, not in every individual case. The French femur is longer than that of the Aino, of neolithic man, and of the ancient inhabitants of the Canary Islands. On the other hand, the French femur appears to be slightly less than the Libyan, although the humerus is somewhat greater. The French women appear in all long bones less than the Libyan woman.

late size is concerned. he has made only about half her progress in variation, and hardly any progress at all in correlation.

(vii.) The causes (e. g., lessening of selection) which lend to increase variation may also increase correlation. In other words, the intensity of the struggle for existence is not necessarily a measure of the intensity of correlation.*

The measurements made by Mr. Warren on the Libyans, the results of which he has kindly favored us with, are, on the whole, fairly in accordance with the above conclusions. He finds for the—

Mean of the sexual ratio of		the means	1·092
"	"	" the variations..	1·028
"	"	" the correlations	1·008

The corresponding quantities for the French are: 1·109, 0·930, 0·956, or, we concluded, that in passing from uncivilized to civilized peoples, from Libyan to French, the men gain on the women in size, here very slightly, and the women gain upon the men very markedly in variation and correlation.

These results are merely suggestions, but they may possibly serve to emphasize the importance of a careful measurement of the long bones of, say, 100 members of both sexes for a series of civilized and uncivilized races. In the former case at least there does not appear to be any real difficulty, except the need of co-operation, in obtaining measurements similar to those of M. Rollet, for both English and Germans. The value of such statistics for comparative purposes would be very great.

ALICE LEE,
KARL PEARSON.

* The mathematical theory of selective correlation shows that the close selection of an organ, say the femur, may actually tend to reduce the correlation between two other organs, say the humerus and the radius.

AVALANCHES.

THE causes and effects of avalanches have been known for so long a time that it is unnecessary for us to dwell upon the subject. There are, however, two kinds of avalanches—those that are looked for and those that take place unexpectedly. The former of these are the ones that, as a consequence of the conformation of mountains, have worn away a path that they follow regularly every year and that are called by the name of the place where they fall. Among these, and one of the most important in the region of Davos Platz, is the one that falls at the place called Schwabentobel (Fig. 1) upon the post road running from Davos to Thusis (Grisons). As such avalanches are expected, methods of defense and relief are provided against them, such as the construction of tunnels or parapets upon the mountain side. Fig. 2 shows what a quantity of snow an avalanche carries with it.

An avalanche that belongs to this category is the one represented in Fig. 3, which falls regularly from the Schwarzhorn behind the hospital of the Fluela (passage of the Fluela from Davos into the Engadine).

These avalanches, being foreseen, generally prove harmless, but such is not the case with those that we place in the second category; for instance, take the one that fell on the sixth of February, 1897, at about a hundred yards from the hospital of the Fluela and buried five men and eight horses. Two convoys were crossing over the road when a formidable noise was heard coming from the Weisshorn tirat. Before a single person could stir, men, horses and wagons were swept away like bits of straw by the wind of the avalanche, and the men and horses probably asphyxiated before being thrown against the opposite wall (Schwarzhorn) and covered by the avalanche.

The snow that fell for four hours covered this scene of horror, and at present we would scarcely suspect that there had been an avalanche at the place where the mail passes. And yet the road is a hundred feet above the true one.

The avalanche was 1,300 feet in width and passed over an extent of about half a mile. At a place where two horses and three men were found the avalanche was from 50 to 65 feet in depth. There are two bodies that have not as yet been found, after a search of more than three months. It is supposed that they are at the bottom of the avalanche, and it will be necessary to wait until the snow melts in order to recover them.

Upon these heights (the passage is at an altitude of 7,870 feet) there are no trees or other vegetation to hold avalanches back, and so their effects are always terrible, and there is not a year passes in which a few deaths do not have to be recorded.

The figures that accompany these few lines reproduce photographs that were taken by M. Sigrist Hender at Davos-Platz. They give an idea of what an avalanche of snow is in the mountains of Switzerland.—M. Picard, in La Nature.

THE PRODUCTION OF PRECIOUS STONES IN 1895.

UNDER this title Kunz* reviews the chief features of the gem industry for the year, giving specially copious details concerning the American production.

A six carat diamond was found at Saukville, Wis., six miles from Milwaukee. In California several diamonds were found, one at Alpine Creek, Tulare County, five near Oroville, Butte County, and about as many more from near the "head of the creek," probably referring to one of the sources of the Feather River. From the association with peridotite, it seems probable that more may be found in this region.

In South Africa the De Beers Company produced diamonds to the value of about $15,000,000 in the year ending July 1, 1895, and the output of the same company for 1896 has been sold for $36,000,000. The total of the dividends paid by the South African diamond companies in the past ten years has been $58,000,000. A 640 carat diamond called the Rietz, found in 1895, is superior in quality to the Excelsior (971 carats) discovered a year or two earlier. The extent of the South African deposits is much greater than hitherto supposed, and many new workings are being opened. Near Winburg, in the Orange Free State, diamond diggings of a prehistoric race were discovered.

Stutzer states that the diamonds of New South Wales occur in a Tertiary (?) deposit, and may have been derived from an intrusive mass of peridotite, now serpentinized. They are said to be of better quality than those from South Africa.

The great advance in the price of carbonado, which has trebled in value, has stimulated the search for substitutes. The only source of carbonado is Bahia, Brazil, where a single lump, weighing 3,073 carats, was found during the year. The practicability of using artificial diamonds seems improbable in the light of Moissan's experiments, who has made several hundred crystals with a total weight of about ½ carat on an outlay of $2,000. This is about 2,000 times the value of natural diamond powder.

Mr. Kunz has named the hydrocarbon to which the phosphorescence of certain diamonds is attributed, Tiffanyite.*

Rubies have been found in place near Franklin, Macon County, N. C., in decomposed gneiss with garnets and chlorite.

Brown and Judd † have recently described the occurrence and methods of obtaining the rubies of the noted Burmese mines, where the paragenesis is much like that of the corundum at Orange County, N. Y., and Sussex County, N. J. In Siam rubies and sapphires have been obtained during the past few years from the Pailin Hills. From Black Creek, New Zealand, rubies are also reported. Sapphires and a few rubies are gotten by sluicing the detritus of a decomposed limestone in Fergus County, Montana. The outlook in this locality is promising. The Montana rubies and sapphires are extremely varied in color.

A number of rich green tourmalines were found in 1895 at Mount Mica, Paris, Me. Five of these were cut into gems of from five to fifty-seven carats in weight. At Haddam Neck, Conn., five hundred dollars' worth of tourmalines of various colors were obtained.

Turquoise is reported from Cripple Creek and from Castle Rock Spring, Col. A mixture of prosopite and quartz closely resembling turquoise was found at Provo, Utah.

Unusually fine opals from near Salmon City, Idaho, as well as other occurrences of opal in Idaho, Washington, Oregon, Arizona, California, Colorado and Georgia are mentioned. Australian opals were sold for more than $100,000 in 1895.

In addition to the above named gems, mention is made at greater or less length of andalusite, cyanite, garnet, quartz, amethyst, chrysoprase, plasma, moss agate, labradorite, lapis lazuli, thalcebrusite, realgar, amber, xenotime and monazite.

The total value of the gem production in the United States for 1895 is placed at $113,621, of which $50,000 is accredited to turquoise.—American Naturalist.

CLOUD AND WAVE STUDIES.

THE old days of blank white skies have practically passed away so far as the walls of our exhibitions are concerned, and even the beginner in photography now desires to obtain clouds either on the same negative as his landscape or on a separate plate. It is not

difficult to obtain clouds at the same time as the landscape, provided a few precautions are taken.

The simplest way to obtain clouds simultaneously with the landscape is to use isochromatic plates with a yellow screen, the sole purpose of the latter being to cut down the strongly actinic blue light from the sky. The particular depth of screen is a matter of judgment, though as a rule the palest that of commercial screen is quite deep enough for all ordinary clouds, and it is only when the light, feathery cirrus—so well known as the mackerel sky—appears that a darker screen need be used.

Even with ordinary plates clouds may be obtained if a foreground shutter be used—and there are one or two cheap double drop or window blind shutters on the market which are very effective. The only thing to be careful about is to note that the aperture of the shutter is sufficiently large not to cut off the illumination of the corners of the plate. With one of these shutters it is possible, by carefully manipulating the strings actuating the sliding pieces, to give at least four or five times more exposure to the foreground than to the sky, and without the slightest sign of a line of demarkation, provided the sliding pieces are kept on the move. If such a shutter be used with an iso plate and yellow screen, far better results can be obtained, and the yellow screen may be entirely done away with.

When it is desired to obtain clouds on a separate plate, care should be taken not to point the camera too high, and to include, as far as possible, a small portion of the landscape as well. The lens need not be stopped down very much—about $f/11$ or $f/16$ will be quite enough—and with a rapid plate and a shutter working about $\frac{1}{25}$ of a second, good clouds can be obtained. If a yellow screen is used the exposure may be increased to $\frac{1}{8}$ second, or even more if a very dark screen be used, but this is unnecessary unless the clouds are really required for meteorological and not pictorial purposes. Too short an exposure makes it difficult to obtain correct rendering of the sky, just as too dark a yellow screen will have the same effect. On the other hand, too long an exposure will cause the cloud forms, particularly if at all delicate, to be entirely lost. Almost as important as the exposure is the development of the cloud negatives—and care should be taken not to push development too far, so as to obtain too great a contrast, and yet, at the same time, negatives which are too thin will not print well. There is one little point in connection with printing in of clouds, particularly on gelatino-chloride paper, and that is to see that the cloud negative is approximately the same color as the landscape, for, if not, the final tone of the sky will be totally different. This is particularly noticeable when a sky is tinted by sunning down with a card, while the landscape may have been printed from a yellow stained negative.

When we desire to obtain clouds and wave studies combined, it will be found that all the directions given above will be satisfactory. One of the greatest mistakes in the taking of wave studies is to drive the shutter too quick. This means that the wave looks frozen, while with a longer exposure there is some fuzziness which gives one a far better idea of moving water. Even for quickly moving water, less than $\frac{1}{50}$ of a second is rarely required.—Photographic News.

INSANE JOURNALISTS.

"In several of the English lunatic asylums," says a writer in a French medical periodical, "the management has had the happy and original idea of introducing journalism among the inmates as a curative measure, and according to the reports furnished annually, the innovation has been attended with the best effects. Some of the physicians even declare that in many instances they have been indebted to the lucubrations of their patients for valuable hints as to the best way of treating them. One demented person, for example, obstinately refused to take any food, and with equally invincible stubbornness declined to furnish any reason for his refusal. There was no difficulty, however, in persuading him to commit his thoughts to paper, for apparently the cacoethes scribendi is quite as powerful among people who have lost their wits as it is among those who have contrived to preserve them, and at once this individual's peculiar delusion was made manifest. This is what the hitherto intractable monomaniac wrote: 'I desire to be buried as quickly as possible. It is a monstrous scandal that I should be compelled to drag about all over this house a dead and putrefying corpse.' As soon as the bent of the patient's weak-mindedness was thus brought to light, he received appropriate treatment, and is said to have eventually recovered." The French commentator selects the New Moon, which he justly regards as very appropriately named, for especial commendation, but he omits to say where this journalistic luminary rises. He quotes from it the following passage, which shows, at all events, that a sense of humor is compatible with lunacy: "Wanted for a throne, which it would be indiscreet to specify at present, an emperor or king who is thoroughly conversant with the business. It is quite useless for the Czar of Russia to reply to this advertisement." We may inform our contemporary that journalism by lunatics for lunatics is by no means a novelty in our establishments for the insane. Writing in 1857, Dr. Andrew Wynter said, with reference to Murray's Royal Asylum at Perth: "Not content with these efforts, they seem to think that they are nothing unless critical, and accordingly they have set up a journal in which they review their own performances. The first number of Excelsior is now before us, in which we find poetry, news, and criticisms on music and contemporary literature; and he who reads with the idea of finding anything odd in this production will most certainly be mistaken, for no one could divine that there was a 'bee in the bonnet' of printer, publisher, and contributor." Any one interested in the history of lunacy and its treatment in modern times will find much curious information in Dr. Andrew Wynter's article. It was published, together with several other papers by the same author, by Mr. Robert Hardwicke, of Piccadilly, in a volume called "Curiosities of Civilization"—having appeared previously in the Quarterly Review, says the Lancet.

It is stated by one of the heads of departments of the London and Northwestern Railway that that company issues yearly fifty tons of railway tickets.

THE
Scientific American Supplement.

PUBLISHED WEEKLY.

Terms of Subscription, $5 a Year.

Sent by mail, postage prepaid, to subscribers in any part of the United States or Canada. Six dollars a year, sent, prepaid, to any foreign country.

All the back numbers of The Supplement, from the commencement, January 1, 1876, can be had. Price, 10 cents each.

All the back volumes of The Supplement can likewise be supplied. Two volumes are issued yearly. Price of each volume, $2.50 stitched in paper, or $3.50 bound in stiff covers.

Combined Rates.—One copy of Scientific American and one copy of Scientific American Supplement, one year, postpaid, $7.00.

A liberal discount to booksellers, news agents, and canvassers.

TRANSPORTATION OF THE PACKING CASE CONTAINING THE BALLOON, JUNE 14, 1897.

INSPECTION OF THE BALLOON, JULY 2, 1897.

ANDRÉE'S POLAR EXPEDITION.

ANDRÉE'S POLAR EXPEDITION.

The recent departure of Andrée has once more centered our attention on those northern islands which have so often been the starting place of polar expeditions. Quite fresh in our memories is the sailing of the Fram, and Nansen's home-coming, yet we follow with renewed interest the moves of the daring balloonist, who in his turn defies the prowess which guards the Arctic regions and the pole. It will be remembered that Andrée purposed to enter upon his perilous enterprise last year, but that contrary winds prevented him from carrying out his plan at that time. To avoid the repetition of this turn of events, if possible, and to make sure of his opportunities, Andrée set out for Danes Island fully a month before time. He left Stockholm on the 18th of May and reached Tromsö in a week on board the fine Swedish man-of-war the Svensksund. From Tromsö another nine days or so took him to Danes Island. There he found the balloon house erected the year before still well preserved. Probably a dense snow cover had protected it against the rigor of the Arctic winter. Some alteration had, however, to be made, an addition to the balloon making increased storage room necessary. The diameter of this octagonal building, of which we give an illustration, is 78 feet; the side toward the south, that is, toward the hill, is 65 feet high; the front measures only 57 feet in height. The front was to be torn down as soon as the right wind—the southeasterly wind—set in. The site of this storage house was well chosen. One inducement to its adoption lay in the previous location there of Pike's little wooden hut. Pike, an English sportsman of means, made this place his station, from which he started his hunting expeditions. The house was unoccupied of late, on account of an illness of its owner, and had been placed at Andrée's disposal. We give a cut representing this hut, on the left hand side of which can be seen the gas generating plant. Andrée availed himself of the log house mostly as a store house for his provisions and as a pigeon loft. With regard to the attempts at sending messages with these birds, we fear that they were scarcely promising. The pigeons sent last year did not reach their destination, and probably they were attacked and overpowered by the large Arctic birds on Bears Island, which lies on the way to the continent, and where the winged message bearers rest on the way.

On the 14th of June, the balloon was transported from the Svensksund to its storage house by sledge, as in our illustration. It was filled, and carefully examined for leaks. This is done by applying to the surface of the envelope paper saturated with acetate of lead solution. The sulphureted hydrogen in the gas turns these strips of paper black if it comes in contact with them, and this being a very delicate test, any slight leak is easily detected. The operation involves the scaling of the balloon, and requires considerable agility on the part of the workers. Our illustration will graphically present this fact to our readers.

On the 27th of June, the balloon was announced ready to start. The filling had taken eighty-nine hours, being begun on June 19, and completed on June 22. The provisions, packed in bags, lay ready for shipment, the car was ready, too, and the balloon, with the addition mentioned above, rose to a height of 70 feet. Stretched over it was placed a covering of sail cloth, as a protection against rain or snow, while tight felt strips provided a resistance against the internal pressure.

Of the front of the storehouse two stories were already pulled down. The corner posts could readily be hewn down, so that the balloon could freely emerge to the north. Andrée intended to make his ascent on July 1; however, the wind was predominantly from the north.

The Gunboat Svensksund.

THE BALLOON HOUSE IN VIRGO BAY, DANES ISLAND.

Gas pipe to balloon.

PIKE'S LOG HOUSE ON DANES ISLAND AND GAS WORKS.

On the 11th of the same month, all being ready and the breeze blowing from the south, Andrée, with his companions' assent, gave orders for departure. Before ascending, the head of the expedition sent telegrams to the King of Sweden and to his Swedish fellow citizens, the former to express his gratitude for the support given, the latter to give notice of his starting and to tender his farewell.

Then the ascent began. It took place under altogether favorable circumstances, amid a thunder of cheers and godspeeds. The balloon rose some 650 feet, then sank again to sea level, and finally ascended for good after the aeronaut had thrown some ballast. With a velocity of about 22 miles per hour it was carried north, remaining in sight for one hour.

The 13th of July the Svensksund left Danes Island on its return journey, and during the whole time of crossing faced a southwesterly wind; perhaps in the further north the aeronauts were fortunate enough to find what they hoped for—a more favorable wind.

ANDRÉE'S BALLOON, THE ADLER.

Andrée started with the same absolute confidence in his craft which has so fortunately led Nansen on his expedition; let us hope that, like his sea faring predecessor, Andrée will be safely brought home, and that his return may mark a new period of advance, of additional knowledge gained in a field which for centuries has called the braves of many nations to risk their lives for the sake of science and in search for truth.

Our illustrations are taken partly from L'Illustration and partly from Illustrirte Zeitung.

The stock company for automatic sale in Germany has received permission to place in the post offices of Berlin automatic machines selling post cards and stamps. For their trouble in putting up these automatons the company are permitted to sell by a similar machine on their own account post cards with local views.—Uhland's Wochenschrift.

THE FLORIDA SPONGE INDUSTRY.

By WILLIAM B. BURK, in the American Journal of Pharmacy.

SPONGE is a substance with which almost every one is familiar, as there are but few living in civilized communities who do not find occasion to use it for a great variety of purposes. The article is so very useful that a large number of inconveniences would arise if it could not be obtained. Without it, what would the surgeon, the traveler or the housekeeper do? And yet most of those who use sponges in an infinite variety of ways all their lives never stop to consider how they are formed; that is, whether they are plants or animals, or what their history or habits may have been.

Sponges consist of a framework, or skeleton, coated with gelatinous matter and forming a non-irritable mass, which is connected internally with canals of various sizes. The ova are very numerous, and present in appearance the form of irregular shaped granules derived from the gelatinous matter which grow into ciliated germs, and, falling at maturity into small canals, are then expelled through the orifices. When alive the body is covered by a gelatinous film, which, being provided with cilia, causes a current of water to pass in at the smaller pores and out at the larger apertures, the sponge probably assimilating the nutritive principles contained in the water.

Sponges are found abundantly in tropical waters generally. They gradually decrease in numbers toward the colder latitudes till they become entirely extinct. They vary in shape. Some are shaped like a vase, others are semi cylindrical, others flat like an open fan, and some are round.

The commerce in sponges is of considerable importance. The great difficulty which is experienced in any attempt to distinguish species results from the extreme susceptibility of all keratose sponges to any change in external conditions. They appear to require, for the production of the forms in abundance, tropical or subtropical seas, and attain by far their greatest development in the number of the forms and species in the Gulf of Mexico and West Indian Seas. The typical forms, the commercial sponges, are essentially confined to the waters of the Bahaman Archipelago and the southern and western coasts of Florida in the western hemisphere and to the Mediterranean and Red Seas in the other.

The Florida sponge grounds form three separate and elongated stretches along the southern and western coasts of the State. The first includes nearly all of the Florida reefs, the second extends from Anclote Keys to Cedar Keys, and the third from just north of Cedar Keys to Saint Mark's. The Florida grounds have a linear extent of about 120 miles, beginning at Key Biscayne, in the northeast, and ending in the south at northwest channel, just west of Key West. The northwestern half of the grounds is very narrow, having an average width of only about five miles, and being limited to the outer side of the reef. At about the Matecumbe Reefs the grounds broaden out so as to cover the entire width of the reefs, which are much broader here than at the north. The entire southern half of the grounds has more or less of the same breadth, which is about 13 or 14 miles.

The second sponging ground begins just south of Anclote Keys, with a breadth of 7 or 8 miles, which it maintains from a point opposite Rat Fort to Sea Horse Reef, just south of Cedar Keys. The total length of this sponging ground is about 60 geographical miles. Its distance from the shore varies somewhat. At the south the inner edge approaches within 4 or 5 miles of the mainland, and comes close upon Anclote Keys; but throughout the remainder of its extent it is distant 6 to 8 miles from the shore until it touches the shallow bottom and reefs of Cedar Keys. The depth of water on these grounds, as indicated on the coast survey charts, ranges from 3 to 6 fathoms, but many portions are undoubtedly shallower than this. The northern ground, which maintains a nearly uniform width throughout, is about 70 miles long by about 15 miles broad. It approaches to within about 5 miles of the shore and terminates just off the mouth of Saint Mark's River; the depth of the water is the same as upon the next one to the south, i. e., from 3 to 6 fathoms. The total area of the Florida sponging grounds, which are now being worked, including also those that were formerly fished upon, but have since been more or less abandoned, may be roughly stated at about 3,000 square geographical miles. This probably does not include all of the sponging grounds occurring in Florida waters, for the fact that new areas are being constantly discovered would indicate that there might still be more to find, and it is certain that no strenuous efforts have yet been made to extend the grounds already known, the discovery of new ones having generally been made by accident.

The sponge fishery of the Florida coast differs from that of the Mediterranean in that sponges are not obtained by divers, but by means of a long hook fastened to the end of a long pole and managed from a small boat.

In Florida small vessels of from 5 to 50 tons measurement are employed to visit the grounds, to afford quarters for the men and to bring home the catch. These vessels are generally of light draught and schooner rigged, having proportionately large decks on which to carry boats, working gear and the sponges caught. The holds are of considerable size, for storing the sponges, and the cabins generally small, indicating a sacrifice of comfort to working room. Each vessel carries, according to its size, from five to fifteen men, one as cook and the remainder as fishermen, and also a small yawl boat to every two fishermen, to be used by them in securing the sponges. In addition to the working tools for taking sponges, they are provided with a sufficient quantity of provisions, wood and water for the trip, lasting from four to ten weeks.

The working outfit for a Florida sponging vessel consists of a few small yawl boats, called dingies, and a supply of sponge hooks and sponge glasses. The boats used are always made as light as possible. They are from 15 to 20 feet long and from 4 to 6 feet wide. The idea is to have the boats light enough to enable two men to haul them in and out over the side of the vessel, and yet strong enough to withstand the rough handling which they are sometimes subjected to, and to carry the heavy loads resulting from a day's catch. While catching sponges it is necessary to scull the small yawl boats (dingies) from the stern, and, for convenience in doing so, this form of sculling notch is used. A piece of oak plank about 6 inches wide and 1 foot long is notched at one end to fit the oar and inserted at the other between two guiding strips well fastened to the stern sheet. This sculling notch is placed at one side of the center of the stern sheet and is made to be easily removable in order that it may be taken out of the way when not needed. The sponge hooks are made of iron with three curved prongs, measuring about 5 to 8 inches in width. The entire length of a hook is about 8 inches, the upper end being made into a very strong socket for the insertion of the pole.

The sponge glass is made from an ordinary wooden bucket, the wooden bottom being replaced by one of ordinary window glass securely fastened by cement. In using a sponge glass it is placed upright on the surface of the water, and the handle of the bucket is placed on the back of the neck of the fisherman with his head thrust down in the bucket. In this way the fisherman can distinctly see very small objects in very deep water, and he can easily distinguish good sponges from those of an inferior grade.

When the sponger discovers a suitable sponge through the aid of the sponge glass, he hurriedly grasps his hook, and, plunging it directly upon the sponge, he skillfully pulls it from its habitation and brings it up to the surface and places it in the boat. As soon as the fisherman collects a sufficient quantity, he takes them to the vessel, where they are spread carefully on the deck in their natural upright position, so as to allow the slimy matter, called "gurry" by the sponger, to run off. During the first stages of decomposition they have a very unpleasant odor, something like decayed fishy matter. After the dingies collect sufficient sponges to make a vessel load, they are taken to what are called sponge crawls, which is an inclosure of about 10 to 12 feet, made generally by placing stakes in the beach where the water is from 2 to 3 feet deep.

Sponges, after being kept on the decks of the vessel

from one to two days, will generally be sufficiently cured to be taken to the crawls, where they are kept for a few days and then thoroughly washed and pounded with a flat stick. They are then placed upon strings of about 6 feet in length and taken to the markets, where they are sold at auction. They are generally sold in lots, and then carefully trimmed and packed in bales weighing from 15 to 100 pounds each, according to quality, the cheaper grades being generally packed in the larger bales.

The principal varieties of sponges found in Florida are the following: Sheep wool, yellow and grass. The Florida sheep wool are the best quality, being of very fine texture, soft and very strong and durable. The yellow sponge is of fine quality, but not strong in texture, and not near so soft or durable as the sheep wool sponges. The grass is very much inferior to the others, not being as strong nor so desirable in shape, and being easily torn.

There are no sponges found in the world to equal the Florida sheep wool for softness and strength, and no better bath sponge can be found than a good solid Florida sheep wool, although they are generally sold for washing carriages, etc. In former years Florida sponges were loaded with lime or sand in order to decrease the price, but of late very few loaded sponges have been placed upon the market.

Sponges in great variety are also found in many places in the West India Islands and in Cuba. The Cuban sponges are the next best to the Florida. The principal varieties found in Cuba or the West Indies are sheep wool, reef, yellow and grass, also velvet, which are next best to the sheep wool.

The finer grades of sponges are found principally in the Mediterranean, such as the fine surgeon's, toilet bathing and nursery sponges, and they are very much higher in price than any others.

Florida produces nearly double the amount of sponges that are imported from all other countries, that is, in value, not quantity, and the demand for good Florida sponges is considerably greater than the supply. Consequently, the prices must advance from year to year. The prices have more than doubled within the last twenty years for Florida sponges.

The fine, soft species of sponges, such as surgeon's, toilet, nursery, bath, etc., are found in great variety in the Mediterranean, and are fished principally by divers, sometimes at great depth. After being brought to the land they are buried in the sand and allowed to decompose, after which they are well washed and beaten with a small stick, and then packed in bags and sent direct to London, and again thoroughly cleaned and packed in cases according to size and quality. The large London dealers have almost complete control of the sponges found in the Mediterranean. There are a great many varieties found there, principally the fine surgeon's, toilet, bathing, potter's, fine thin flat (called elephant's ears by the native fishermen), fine cups, Zimocca toilet, Zimocca potter's, etc. Some of the finest cup sponges are sold at as high as $100 per dozen. The Mandruka bath sponges are also very expensive and very rare. Some of the cheaper species are also found in the same waters, but none like those found in Florida or Cuban waters.

ON THE DISTRIBUTION OF THE PELAGIC FORAMINIFERA AT THE SURFACE AND ON THE FLOOR OF THE OCEAN.

THE pelagic Foraminifera play a most important role in the economy of the present ocean, as well as in the geological history of our planet. Living specimens of these pelagic Protozoa are distributed everywhere in the surface waters of the open ocean, about fifteen or twenty species being met with in the surface waters of the tropics, and one or two dwarfed species are captured among the floating icebergs of the Arctic and Antarctic regions. The dead shells of these Foraminifera make up by far the larger part of the carbonate of lime present in the deep sea deposits known as Pteropod and Globigerina oozes, which cover about 50,000,000 square miles of the ocean's bed. In addition, they make up the major part of the carbonate of lime present in the other deep sea deposits, such as diatom ooze, radiolarian ooze, red clay, and the deeper terrigenous deposits which are laid down in close proximity to continents and oceanic islands. Indeed, it may be said that, taken as a whole, nine-tenths of the carbonate of lime in marine deposits from depths greater than one hundred fathoms is derived from the dead shells of the pelagic Foraminifera.

When the Challenger set out on her cruise around the world, all the naturalists of the expedition believed that the habitat of the Globigerinae was on the seabed in deep water. This opinion was held by Wallich,* Carpenter, and Wyville Thomson. Gwyn Jeffreys, however, took another view; he regarded the Globigerinae as surface organisms, and the Globigerina ooze as made up of dead shells which had fallen to the bottom from the surface waters. The fact that McDonald† and Major Owen had captured several species of these Foraminifera in tow nets at the sea surface appears to have been overlooked or forgotten. Huxley discussed this question, and while not coming to any definite conclusion on the subject, he held that the balance of evidence was in favor of those who maintained that the Globigerinae lived on the bottom of the ocean.

During the first few months of the Challenger expedition the attention of the naturalists was almost wholly taken up with the examination of the deep sea organisms obtained in the trawl and dredge, and with the larger animals procured at the surface. When, however, the expedition entered the tropics, I frequently observed Globigerinae, Orbulinae, Pulvinulinae, and Sphaeroidinae at the bottom of the glass globes into which the contents of the surface nets were washed, and the attention of Wyville Thomson and the other naturalists was called to the fact. It was Wyville Thomson's opinion, however, that these shells really came from the deep sea deposits. It was the custom to sift and wash large quantities of the ooze procured in the dredge on the deck of the ship, and it was believed that some of the shells from the deck being washed overboard were subsequently caught by the tow nets dragging astern. But the appearance of the shells taken in the tow nets was so different from that of those procured from the bottom that I could not accept the above explanation. When the weather permitted, the tow nets were dragged, at considerable distances from the ship, from a rowing boat, and Foraminifera were procured in abundance. By using a water glass I was sometimes able to dip up a single specimen in a glass beaker without in any way touching it. When this

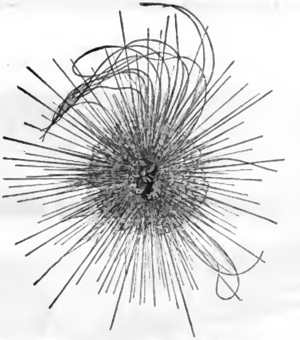

FIG. 1.—Hastigerina pelagica (d'Orbigny) [murrayi, Wyville Thomson] with floating apparatus and pseudopodia extended, as found floating on the surface.

specimen was taken on board the ship, and placed under the microscope, the whole sarcode of the animal was to be seen expanded outside of the shell, as represented in Fig. 1. When our attention was once directed to the subject, the pelagic Foraminifera were observed in almost every haul of the tow net. Many of the Globigerinae, the Orbulinae, and the Hastigerinae are furnished with long spines, and when the animal is expanded the sarcode rests between the spines. In the Pulvinulinae, the Sphaeroidinae, and Pullenine, which

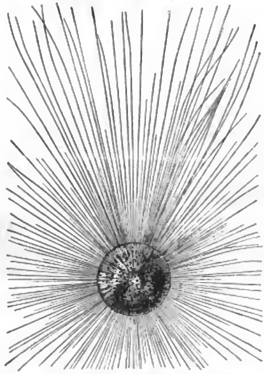

FIG. 2.—Orbulina universa (d'Orbigny), from the surface.

have no spines, the shell is frequently so hidden in the expanded yellow-colored sarcode that it may escape observation.

On the return of the Challenger expedition, the late Mr. H. B. Brady and others pointed out that, if the Globigerinae were pelagic organisms, it was a most extraordinary circumstance that no naturalist had recorded them in any of the numerous tow net gatherings about the British coasts. This, however, quite agreed with the experience of the Challenger naturalists. Whenever the ship entered a bay, an estuary, or indeed any coastal waters, the pelagic Foraminifera became very rare or entirely disappeared from the nets, although they may have been abundant fifty miles from the coast. I have never seen a single specimen in the tow nets around the coasts of Scotland. In the Triton and Knight Errant expeditions pelagic Foraminifera were found in abundance in the Gulf Stream waters which flow up the Faroe Channel, although not a single specimen was observed in the Minch or North Sea waters. The pelagic Foraminifera are truly oceanic creatures, even more so than the pteropoda; they are most abundant in true oceanic currents; where these currents flow directly toward a coast they may be borne close to the shore, but usually they are only to be met with far out at sea.

From an examination of the large number of microscopic preparations and tow net gatherings made during the Challenger expedition, the following species of Foraminifera have been recognized as pelagic:

Globigerina sacculifera, Brady; Globigerina aequilateralis, Brady; Globigina conglobata, Brady; Globigerina dubia, Egger; Globigerina rubra, d'Orbigny; Globigerina bulloides, d'Orbigny; Globigerina inflata, d'Orbigny; Globigerina digitata, Brady; Globigerina cretacea, d'Orbigny; Globigerina dutertrei, Brady; Globigerina pachyderma (Ehrenberg); Globigerina

* The North Atlantic Sea Bed. London, 1862; also Deep Sea Researches on the Biology of Globigerina. London, 1876.

† See Huxley's Appendix to Dayman's Report on Deep Sea Soundings in the North Atlantic made in H.M.S. Cyclops in June and July, 1857. London, published by the Admiralty, 1858.

marginata (Reuss); Globigerina linnaeana (d'Orbigny); Globigerina helicina, d'Orbigny; Orbulina universa, d'Orbigny; Hastigerina pelagica (d'Orbigny); Pullenia obliquiloculata, Parker and Jones; Sphaeroidina dehiscens, Parker and Jones; Candeina nitida, d'Orbigny; Cymbalopora (Tretomphalus) bulloides (d'Orbigny); Pulvinulina menardii (d'Orbigny); Pulvinulina tumida, Brady; Pulvinulina canariensis (d'Orbigny); Pulvinulina micheliniana (d'Orbigny); Pulvinulina crassa (d'Orbigny); Pulvinulina patagonica (d'Orbigny).

Cymbalopora bulloides* (Fig. 3) can hardly be regarded as a true pelagic Foraminifer. It was only captured in the neighborhood of coral reefs, and the curious thing about it is that not a single specimen was taken containing ordinary sarcode, similar to that observed in the other species of pelagic Foraminifera. In all the specimens the shells were filled with immense numbers of minute zoospores; these latter spread over the field of the microscope in a cloudlike swarm when a shell was broken under the cover glass.

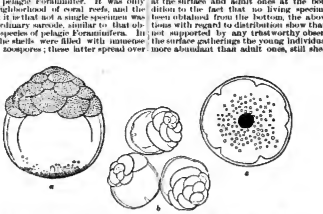

FIG. 3.—Cymbalopora (Tretomphalus) bulloides (d'Orbigny). a, large surface specimen; b, small (young) specimens from the same gathering; c, distal face of the balloon-like chamber, showing the entosolenian orifice, seated in a slight depression. All magnified 60 diam.

The usual color of the sarcode of the pelagic Foraminifera is yellowish brown. In Hastigerina it is bright red, from the presence of red colored oil globules and pigment. This red color enabled me to pick up this species with a beaker on the sea surface more easily than other species. In Globigerina bulloides (hirsuta) and aequilateralis the yellow orange color of the sarcode is due to the presence of numerous oval-shaped xanthidia, or "yellow cells," similar to those found in the Radiolaria. When the sarcode with these "yellow cells" flows out of the foramina, and mounts between the numerous spines outside the shell, the whole presents a very striking object under the microscope; the transparent sarcode can be seen running up and down the long silk-like spines, and the "yellow cells" seated at the base of these spines quite obscure the body of the shell.

The majority of the species in the above list occur within the tropics, and the thick-shelled species occur only in warm water, such as Sphaeroidina dehiscens, Pulvinulina menardii (Fig. 4), Pullenia obliquiloculata, Globigerina conglobata and sacculifera. The number of species becomes less in the temperate regions, Pulvinulina micheliniana and canariensis, Orbulina universa (Fig. 2), Globigerina bulloides and inflata being the prevailing forms. In the Arctic and Antartic regions Globigerina dutertrei and pachyderma, together with very minute specimens of Globigerina bulloides, appear to be the only forms present in the surface waters. The gradual disappearance of the tropical species, and their replacement by other species, as the colder water to the north and south of the equatorial regions is entered, has always appeared to me rather puzzling, especially when it is remembered that these changes take place in a continuous oceanic current, like the Gulf Stream, flowing from the equator toward the poles. It sometimes seemed as if the one form slowly passed into the other with the changed conditions of surface temperature.

The same species inhabit all the great oceans, but in the Indian and Pacific Oceans certain species appear to predominate, for instance, Pullenia obliquiloculata

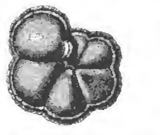

FIG. 4.—Pulvinulina menardii (d'Orbigny), from the tropical deposits.

and Globigerina aequilateralis; on the other hand, Pulvinulina menardii and Globigerina rubra appear to be more abundant in the tropical Atlantic.

The species inhabiting the north and south temperate regions and the species inhabiting the two polar regions appear to be nearly if not quite identical.

The distribution of the dead shells of the pelagic Foraminifera on the floor of the ocean corresponds exactly with the distribution of the living specimens at the surface of the sea. It has sometimes been urged that the dead shells of tropical species might be carried a long way to the north or to the south by oceanic currents, but this does not seem in any way to be the case; the distribution of the dead shells on the bottom does not appear to be much if any wider than that of the living specimens at the surface, and this shows that the dead shells must reach the bottom a very short time after the death of the organisms. The fact that the distribution of these shells at the bottom of the ocean is governed by the surface conditions is of itself almost conclusive proof that they live only at the surface, for otherwise their distribution would be similar to that of bottom living, or benthos, species, which is wholly independent of the temperature conditions prevailing at the surface of the sea. Carpenter and Brady at one time held the view that young individuals lived at the surface and adult ones at the bottom; in addition to the fact that no living specimen has ever been obtained from the bottom, the above considerations with regard to distribution show that this view is not supported by any trustworthy observations. In the surface gatherings the young individuals are much more abundant than adult ones, still shells as heavy as any in the deposits are occasionally taken in the surface nets. The young individuals are likewise more abundant at the surface than in the deposit, when compared with the adult shells present; this is especially the case in deposits from very deep water. This arises, as we shall see, from the more rapid solution of the young shells as they fall through the sea water to the bottom.

When examining a deep sea deposit it is always possible to say, from a study of the pelagic shells of the Foraminifera, whether the sample comes from the tropics, the temperate or the polar regions, but from the examination of these shells alone it would be extremely difficult to say whether the specimen was from the northern or southern hemisphere.

Off the Agulhas Bank at the Cape of Good Hope, off the east coasts of Australia and Japan, and off the east coasts of North and South America, oceanic currents from different sources meet and mix, and there is a wide range of annual temperature at the surface. In these positions large numbers of pelagic Foraminifera (as well as other organisms) appear to be killed by the sudden changes of temperature, and consequently there are indications that the deposits, so far as due to these shells, are accumulating more rapidly in these areas than in other situations. It is a curious fact also that in these regions the deposits of glauconite and phosphatic nodules are more abundant than elsewhere.

In a certain sense the course of a surface oceanic current can be traced on the bottom by means of these dead pelagic shells; for instance, the axis of the Gulf Stream is marked out by deposits of Globigerina ooze from the Strait of Florida to within the Arctic circle. No similar warm current enters the Antarctic region, and consequently no true Globigerina ooze is found to the south of lat. 50° S. When the Challenger took her first deep sea sounding after leaving Heard Island (in lat. 60° S.) there was much speculation as to what the nature of the deposit would be. I ventured to say that it would not be a Globigerina ooze, founding that opinion on the fact that only one or two small Foraminifera had been observed in the tow nets for several days. When a white colored deposit was brought on board from 1,260 fathoms the laugh was rather against "the philosophers," for in external appearance it greatly resembled the calcareous oozes of the Atlantic. On examination, however, it was found to be a Diatom ooze with only relatively few Globigerina shells.

The most striking peculiarity in connection with the distribution of these dead shells on the floor of the ocean is the fact that they are wholly absent from all the greater depths of the ocean, although at the surface their living representatives are as abundant over these deep areas as elsewhere. If we suppose a volcanic cone to rise from the greater depths of the ocean up to within 400 or 300 fathoms of the surface, it will be found that the summit of this cone is covered with a calcareous deposit for the most part made up of the dead shells of pelagic organisms. The deposit may contain 90 per cent. of carbonate of lime, and in it every species of shell met with in the surface waters of the region is represented. As we descend the sides of this cone into deeper water, the thinner and more delicate shells, like Candeina and Hastigerina, disappear first from the deposit (along with the Pteropod shells). In about 2,000 fathoms the deposit consists chiefly of pelagic Foraminifera, and the proportion of young shells is much smaller than in the deposits at lesser depths. With increasing depth the whole of these calcareous shells gradually disappear, till at 4,000 and 5,000 fathoms probably not a vestige of them can be traced, and the deposit all round the cone in 3,000 fathoms becomes a red clay with only traces of carbonate of lime in its composition. Again, if we suppose a basin-like depression on the floor of the ocean, the center of which descends to 4,000 or 5,000 fathoms, while the rim of the basin has only a depth of 1,000 or 2,000 fathoms, then, on the rim, deposits of Pteropod and Globigerina oozes will be found with 70 or 80 per cent. of carbonate of lime, while the center of the basin will be occupied by a red clay with probably not a trace of these carbonate of lime shells. The gradual disappearance of these calcareous shells with increasing depth is evidently due to the solvent action of sea water, and especially of deep sea water. In the lesser depths a very large proportion of these surface shells seem to reach the bottom before they are completely dissolved, and accumulation takes place. With increasing depth the more delicate shells are dissolved before reaching the bottom, and accumulation becomes slower and slower, the last traces of these shells observed in the deposits with increasing depth being broken fragments of large Pulvinulinae and Sphaeroidinae. The greater quantity of lime in solution which Dittmar found in the Challenger samples of deep sea water is apparently a consequence of the solution of the pelagic shells here referred to.

During the early part of the Challenger expedition, Wyville Thomson was much puzzled to account for the origin of the fine red clay which occupies the basin-like depressions of the sea bed far from land, and he suggested that this was an ash† left behind after the solution of the carbonate of lime shells. He was led to this view by observing that when the shells were taken from the purest samples of Globigerina ooze, and, after being carefully washed with pure water, were dissolved with dilute acid, a small clayey residue of a red color remained behind. I was not satisfied with this experiment, for I observed that the color of the residue varied in different samples, and it seemed to me that the fine clayey matter had infiltrated the shells after they had reached the bottom. I accordingly collected, in the course of several months, about 10 grammes of pelagic Foraminifera from the surface of the sea. When these shells were dissolved in dilute acid not a vestige of residue was observed. It was subsequently shown that the red clay came from a variety of sources, and that in the deep sea far from continents it was chiefly derived from the trituration and decomposition of floating pumice.‡

During the past year or two I have carefully collected all the available temperatures of the surface waters of the ocean, and from these have constructed a map showing the annual range of temperature in different regions of the ocean. This map shows that the surface of the sea may be grouped into five great zones, viz.: (1) A nearly continuous equatorial zone, where the temperature is high and the range throughout the year does not exceed 10° F. This zone includes all the principal coral reef regions. (2 and 3) Two polar zones, where the temperature is low and the annual range likewise does not exceed 10° F. In these zones there are relatively few lime secreting organisms. (4 and 5) Two regions lying between the equatorial zone and the two polar zones, where a wide range of temperature occurs between the different seasons (the annual range amounting to as much as 50° F. in some places). In these temperate regions the secretion of carbonate of lime appears to be much more active in the warmer than in the colder months. It thus appears that the most favorable conditions for lime secreting organisms are met with in the warm, equable tropical waters of the ocean, and here as a matter of fact we find the greatest development of corals, and the largest number of lime secreting pelagic organisms. In the polar areas and in the cold water of the deep sea there is, as is well known, a feeble development of all carbonate of lime structures in marine organisms.

From experiments which have been carried out by Mr. Irvine and myself at the Granton Marine Station, we have reason to believe that this distribution is dependent primarily on the physical or temperature conditions of the oceanic waters. When carbonate of lime is precipitated by alkaline solutions, such as carbonate of soda, carbonate of ammonia, or carbonate of methylamine, the effect of temperature is very marked, and it appears to be the case that the secretion of carbonate of lime by organisms is of the nature of a fine precipitation in the interior of the soft structures.‡ If we add sufficient carbonate of ammonia to sea water at different temperatures to convert all the lime salts present into carbonate, we obtain a precipitate which varies both in its crystalline form, in amount, and in time of formation. At 32° F. the precipitate begins to form in about six hours as small but distinct crystals

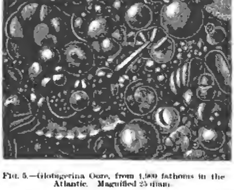

FIG. 5.—Globigerina Ooze, from 1,000 fathoms in the Atlantic. Magnified 25 diam.

of calcite, the quantity in twenty hours amounting only to 0·2 gramme from a liter of water. At a temperature of about 47° F. a mixture of calcite and aragonite is precipitated; at 80° to 90° F. the quantity precipitated is about 0·6 gramme, the precipitate begins to form in from a half to one hour, and it appears to consist of minute crystals of aragonite. It thus seems evident that carbonate of lime would be more easily and more rapidly secreted in the high temperatures of the tropics by means of the effete products of the organism.

As is well known, carbonate of lime in any form is easily soluble in water containing carbonic acid, and the aragonite form is more quickly soluble than the

calcite form in the proportion of about three to two. Both aragonite and calcite are apparently very partially soluble in sea water which does not contain free or loosely combined carbonic acid, but when these dead shells are in contact with decaying organic matter, giving off carbonic acid, they are rapidly dissolved. An experiment with Globigerina ooze in a sea water containing additional carbonic acid showed that the thin walls of the chambers of the shells were first dissolved, leaving rings of the thicker portions of the Pulvinulina shells, for example. Decaying organic matter has a powerful solvent action on carbonate of lime, due to two causes: (1) By the carbonic acid formed as one of the products of this decay, and (2) on account of the formation of sulphides and sulphureted hydrogen, due to the reduction of the sulphides present in sea water.—John Murray, in Natural Science.

EDWARD DRINKER COPE, NATURALIST.*

I.

Bitter constraint, and sad occasion dear
Compels me to disturb your season due;
For Lycidas is dead, dead ere his time
Our Lycidas, and hath not left his peer.†

On the morning of April 13, in a car on my way from a funeral in New York to Washington, a newspaper notice of the death the day before of my old friend E. D. Cope caught my eye. Shocked by the intelligence, I dropped the paper, and memory recalled various incidents of our long acquaintance.

The threnody of Milton‡ in commemoration of his friend Edward King also rose to recollection, and the lines just quoted seemed to me to be peculiarly fitted for the great man just dead. He was, indeed, no longer young and had attained his prime, but he had planned work for many years to come and had well advanced in the execution of some of it. He had truly died before his time and had left no peer; the greatest of the long line of American naturalists was prematurely snatched from science and from friends.

My acquaintance with Cope began in 1859. While looking through the part of the Proceedings of the Academy of Natural Sciences, of Philadelphia, for the month of April, in which my first paper published by the Academy had appeared, I found one by E. D. Cope "On the Primary Divisions of the Salamandridæ." It seems that the papers by Cope and myself had been passed on by the Committee on Publications on the very same day (April 26) and appeared in print in juxtaposition. I had not previously heard of the new devotee of science and read his article with as much interest as my own. A well equipped man had evidently come upon the field, and this was the first of the numerous articles that were destined to appear in an uninterrupted flow for nearly four decades. A few months afterward I met the author in Philadelphia at the Academy. A young man, nineteen years old, about five feet nine or ten inches high, with head carried somewhat backward, and of rather robust frame, stood before me. He had an alert, energetic manner, a pronounced, positive voice and appeared to be well able to take his part in any trouble. His knowledge was by no means confined to herpetology, but covered a wide range of science, and his preliminary education had been good. We afterward met from time to time in Philadelphia and Washington, and found we had many sympathies in common and some differences.

In one of our first interviews we had quite an argument on the nature of the family group in zoology, resulting from criticisms I made on the extended scope he had given to that category in the classification of the salamanders. Another controversy, I remember, had reference to the vertebral theory of the skull. In an article on the venomous serpents, published in the Proceedings of the Academy for 1859, he had defined the group in terms involving the adoption of that theory, and I ventured to dissent from its reality. I had myself been much impressed with it in former days, and when sixteen years old had copied in colors an illustration of Owen's so-called archetype reproduced in Carpenter's Physiology. Subsequently, however, the fact that there was only an approximation to the realization of it in the most specialized of fishes and not at all among the lower or higher vertebrates, with other considerations, turned me from it, and I gave my reasons for dissent to Cope. Ultimately he admitted the force of the argument and also abandoned the theory at one time so popular in England and America.

Our acquaintance thus begun in 1859 continued uninterruptedly till death divided us. We rarely met, indeed, that we did not express difference of opinion respecting some subject, but the difference was never of a serious nature and generally little more than sufficient to enliven intercourse.

The future naturalist was born in Philadelphia on July 28, 1840, and the name Edward Drinker was given to him. He was the descendant of a prosperous line long established in Pennsylvania. His father, Alfred, was a man of cultivated literary taste and did much to train his son's mind in early youth. He had retired from active business and lived in luxurious ease in Germantown, a suburb of Philadelphia. There he had formed an arboretum containing most of the American trees which would thrive in the climate of that region. Amid such surroundings the youthful Cope grew up.

An active and intelligent interest in nature became manifest at a very early age. When only about seven years old, during a sea voyage to Boston with his father, the boy is said to have kept a journal which he filled with drawings of "jelly fish, grampuses and other natural objects seen by the way." When eight and a half years old he made his first visit to the museum of the Academy of Natural Sciences of his native city; this visit was on the "21st day of the 10th month, 1848," as entered in his journal. He brought away careful drawings, measurements and descriptions of several larger birds, as well as of the skeleton of an ichthyosaurus. His drawing of the fossil reptile bears the explanatory legend in Quaker style: "two of the sclerotic plates look at the eye—thee will see these in it."

At the age of ten he was taken upon a voyage to the West Indies.* What were the impressions he derived from that voyage we have not been told. But what has been communicated amply justified Professor Osborn in his declaration that "the principal impression he gave in boyhood was of incessant activity in mind and body, reaching in every direction for knowledge, and of great independence in character and action." His school education was mostly carried on in the Westtown Academy, a Quaker institution about twenty-three miles west of Philadelphia. One of his instructors was Dr. Joseph Thomas, a well known literary worker of Philadelphia and future author of a "Universal Pronouncing Dictionary of Biography and Mythology" (1870), and said to be an "excellent linguist." Under his guidance Cope obtained a passing knowledge of Latin and Greek. He appeared to have had no instruction in any biological science and had no regular collegiate training. He did, however, enjoy the advantage of "a year's study (1858–59) of anatomy and clinical instruction at the University of Pennsylvania," in which the illustrious Leidy was professor of anatomy. But, in the words of his literary executor (Professor W. H. Osborn), "it is evident that he owed far more to paternal guidance in the direct study of nature and to his own impulses as a young investigator than to the five or six years of formal education which he received at school. He was especially fond of map drawing and of geographical studies."†

While a school boy he relieved his studies of the classics and the regular course in which boys of his age were drilled by excursions into the fields and woods. Reptile life especially interested him, and he sought salamanders, snakes and tortoises under rocks, stones, fallen trees and layers of leaves, as well as in the ponds and streams of his vicinage. The trophies of his excursions were identified from descriptions in the works in which they were treated, as well as by comparison with identified specimens in the museum of the Academy. He early and almost without guidance learned to use the library and collection of the Academy, although he did not become a member until he came of age in 1861.

Cope's first contribution to the Proceedings of the Academy appeared in the part covering April and was "On the Primary Divisions of the Salamandridæ, with Descriptions of the New Species."‡ In this maiden paper he instituted important modifications of the systems previously adopted in the United States. He soon afterward catalogued the serpents preserved in the museum of the Academy of Natural Sciences and likewise improved upon the systems previously in vogue. He continued with various papers, describing new species and giving synopses or brief monographs of sundry genera of lizards and anurous amphibians.

For five years his publication was confined almost exclusively to the reptiles and amphibians. (The continuity was only interrupted once, in 1862, when he described a new shrew caught by himself in New Hampshire.) Not until 1864 did he begin to extend his field. In that year he described various fishes and a supposed new whale, and gave his first contribution to paleontology in the description of the stegosaurian amphibian called Amphibamus grandiceps. But although his attention had become thus divided, he never lost his interest in herpetology and continued to the end of his life to devote much attention to that department. His studies extended to every branch of the subject, covering not only specific details and general taxonomy, but also the consideration of anatomical details, the modifications of different organs, geographical distribution, chronological sequence, genetic relations and physiological consequences. So numerous were his memoirs, so entirely did he cover the field of herpetology, and so marked an impression did he make on the science, that he was well entitled to apply to himself the boast of the Virgilian hero, "Pars magna fui."

In his earliest essays he manifested the independence and critical spirit which were so characteristic of him later. One knowing all the circumstances of the case may be amused in coming across a passage expressed in the tones of a veteran published by him when twenty years old: "In proposing the name Zaocys . . . we are giving expression to an opinion long held by us as to the unnatural association of species in the so-called genus Coryphodon. . . . In it we find cylindrical terrestrial species united with compressed subarboricole species, upon a peculiarity whose value as an index of nature appears to us entirely imaginary. The very nature of the coryphodontian type of dentition, as distinguished from the isodontian and syncranterian, would lead us to infer its inconstancy;" and so on.§ Bold as was the criticism of such herpetologists as Duméril, Bibron and Günther, it was justified by the facts, and the young author's conclusions have received the indorsement of the best succeeding herpetologists, including even the latest author criticised.

In 1863 he paid a visit to Europe, partly for the benefit of his health, which had suffered from overwork, and partly for the purpose of seeing the great museums of England, France, Holland, Austria and Prussia. Notwithstanding his ailments, he made good use of his time abroad and systematically examined the collections of reptiles in the chief centers of science. He did not even restrict his studies to herpetology, but extended them to various other subjects.

On his return from Europe, in 1864, he was appointed professor of natural science in Haverford College, an institution chiefly supported by Quakers, but retained the position only three years. During this time, in 1865, he married Miss Annie, daughter of Mr. Andrew Pim, of Chester County, Pa.

In and after 1864, too, he enlarged the range of his studies and publications, and also extended them to ichthyology, mammalogy and paleontology. He had always been interested in the philosophical aspects of science and early adopted the conception of descent with modifications to account for the variations of animals and the differentiation into species and higher groups, and in 1869 began to give expression to his peculiar views.

On the death of his father he became heir to a considerable fortune. Part of this was invested in mines, which for a short time gave promise of good returns, but, it is said, the majority of the stock was held by others, and owing to the incapacity of superintendents and the operations of the controlling stockholders he lost his interests. While in the enjoyment of his fortune he spent large amounts in collections and personally conducted or sent out expeditions to various places. One of the most important was sent to South America. He filled a large house from cellar to topmost story with his collections and resided in an adjoining one.

In 1871 he conducted an expedition to Kansas and especially investigated the Cretaceous beds of that State and collected their fossils. In 1872 and 1873 he became connected with the United States Geological Survey, and for the fossils visited Wyoming in the former year and Colorado in the latter. In 1874 he joined the survey under the command of Lieutenant Wheeler, of the engineers, and explored New Mexico.

The collections made during these expeditions were large, and the unwearied industry and energy, as well as cares, of Cope were rewarded with many well preserved fossils. These were described in many communications to the Academy of Natural Sciences and the American Philosophical Society, and later in large volumes published by the general government as reports of the respective surveys with which he was connected.

The various investigations thus opened were continued through the succeeding years. His collections continued to grow in spite of reduced means. He refused even to sell portions for which he was offered liberal sums and, at the cost of personal discomfort, held on to them and made his home, for much of the time, in the midst of them, having sold his residential house but kept his museum.

In 1878, he purchased the rights of the proprietors of the American Naturalist and removed it to Philadelphia. Professor Packard, one of the original proprietors, co-operated with him in the editing of it for some years and he was also assisted by various eminent specialists.

In this journal numerous articles of all kinds, including reviews and editorial comments, were published by him. His last words appeared in numbers issued after his death, the leading article in the number for June having been written shortly before his death. It treats of the remarkable mammals of South America known as Toxodontia.

THE COMMON ACCIDENTS OF SUMMER TOURISTS.

By JAMES E. PILCHER, M.D., Captain in the Medical Department of the United States Army.

FOREIGN BODIES.

In camping parties particularly, insects are liable to find their way into the auditory meatus and produce great annoyance and sometimes no little pain. It will do no harm to hold a bright light to the ear in the hope that the intruder may be attracted to emerge, but it is better that every person should know how readily foreign bodies can be floated out of the ear by injections of warm water.

The eye is even more subject to travel accidents of this kind than the ear, and unless the body be embedded in the cornea or conjunctiva, which is comparatively unusual, no emergency is more readily relieved. There is no reason why the laity should not understand the simple maneuver of exposing the lining of the lower lid by looking up, while gentle pressure is made just below the eyelid. The drawing of the upper lid down over the lower is equally easy and often effective in removing the foreign body. In case of failure, the removal may be attained by drawing across the eye, under the upper lid, a little corner of a very soft linen handkerchief moistened with the patient's saliva. Sufferers from this accident should be informed that a slight conjunctival abrasion, produced by a foreign body which has been removed, will continue the sensation of the presence of the body even after it has disappeared.

CUTANEOUS ACCIDENTS.

The burns of the stage of rubefaction and sometimes of slight vesication, produced by the exposure to the rays of the sun of persons unaccustomed to outdoor life, are common to summer tourists. The recognition of the fact that this accident is a genuine burn renders its treatment readily understood. The numerous cold creams and other unguents sold in the apothecary shops serve well enough, but nothing can be better for general use in these cases than the carbolated petrolatum everywhere available.

The same may be said of the lichen tropicus or "prickly heat," to which delicate skins are subject in hot weather. The intense itching of this trifling but exceedingly annoying affection is also usually readily brought within the limits of endurance by carbolated applications. The little jar of carbolated petrolatum is a most advantageous constituent of every tourist's summer outfit.

The more severe inflammation produced by contact with the various species of rhus, the "poison ivy," the "poison oak" and the "poison sumac," is often temporarily treated with advantage in the same manner. These injuries, however, pre-eminently come under the category of matters in which the "ounce of prevention" is particularly applicable, and it is well for persons going into the country for an outing to be able to distinguish them from the harmless growths which they resemble.

The beautiful woodbine or Virginia creeper is distinguished from the venomous "poison vine" by the fact that the leaf of the harmless growth consists of five leaflets given off from a common stem, while that of the toxiferous plant has but three leaflets upon the main stem. The "poison oak," or Rhus toxicodendron, may be detected by the same conformation of leaf. The "poison sumac" or Rhus venenata, which produces a cuticular inflammation similar to those already mentioned, may be distinguished from the ordinary harmless sumac by the fact that, instead of bearing close bunches of red berries at the ends of its branches, its fruit consists of slender clusters of small white berries given off from the axils of the leaves.

WOUNDS.

It is difficult to realize that in this day and genera-

tion any person can be so ignorant as to treat slight wounds with anything but cleanliness and gentle pressure. But the cobwebs, tobacco quid and filthy lond heresies all still have enthusiastic partisans, and slight wounds are exceedingly liable to be transformed into poisoned wounds of considerable extent by the employment of such agents. It is well then to impress upon the traveler the fact that in the wounds of no severity simple cleanliness and gentle pressure, maintained by a clean compress held by a clean bandage, comprise all the requisite treatment. It is worth while indeed to go farther and explain that filthy agents should be eschewed in any kind of wound. Why fresh cow dung or dust permeated cobwebs should be considered to possess healing qualities is a question that the wisest cannot answer. But, with the predilection for those dressings which possesses the bucolic mind, it is a most wise precaution to warn contemplating travelers against them and in favor of clean applications, and to explain that anything contaminated with animal secretions is dangerous, from the mucus laden handkerchief to the sweat saturated shirt—clean paper being better than soiled linen, the ink of the printed sheet being rather an advantage than otherwise. The removal of a barbed fishhook by thrusting the point out through the skin, and then, after breaking off the barb, easily withdrawing it, is so simple a procedure that it seems hardly necessary to mention it, but experience has shown how few of the uninitiated bethink themselves of this very natural maneuver. It should also be understood that the temporary treatment for severe wounds, after checking hemorrhage and placing the parts in a comfortable position, is identical with that for slight ones.

BLEEDING.

The most alarming feature of the more severe wounds is the bleeding, which, in case of an injury to an artery, may be dangerous to life. Every person should understand the difference between arterial, venous and capillary bleeding. The bright red hue and spurting flow of the wounded artery should be recognized as an indication of danger promptly to be treated. The fact that pressure between the wound and the heart will control such bleeding should be impressed on every mind. The simple construction of a tourniquet from a large handkerchief, a bit of a garment, a suspender, or any simple article which can be bound firmly about a limb, and the method of tightening the bandage thus created by thrusting under it a rod of any kind and twisting it until the pressure exerted checks the bleeding, should be a part of the elementary knowledge of every one. To this should be added the fact that firm pressure directly upon the wound, in other than arterial bleeding, is the proper method of restraining the hemorrhage. The laity should be cautioned, however, to immediately apply pressure with the hands directly upon the wound, even in case of an arterial injury, until the extemporized tourniquet can be put in place. Death has been known to occur from an arterial wound while the amateur surgeon was so much interested in manufacturing his tourniquet that he neglected to control the bleeding in the meantime.

FRACTURES.

Some points with regard to fractures may be of the greatest value to the summer tourist—the main point being aptly expressed in the Latin motto, noli me tangere. Fractures and dislocations are so frequently aggravated by meddlesome handling that the dictum to do nothing more than place the injured part in the most comfortable position possible for the patient and retain it there, should be most emphatically impressed upon the lay mind. Extemporized methods of immobilizing the parts in the easiest position should be generally understood, including the utilization of canes, umbrellas, sticks and the like as temporary splints to prevent the accentuation of the pain and the aggravation of the injury by motion at the point of fracture.

SPRAINS

are sometimes fully as painful and disabling as fractures, and, like fractures, they should not be made the object of unnecessary meddling. No injury is more frequent with the summer tourist than the sprain, particularly of the ankle. The mode of vacation life, with its admixture of athletic sports and unaccustomed exercise, particularly predisposes to this accident. The laity should learn to avoid arnica, turpentine, and other abominations in favor of immediate immersion in hot water for a considerable period, followed by elevation of the extremity and gentle retention of the parts by a bandage, the material for which may well consist of elastic flannel.

HEAT STROKE

or heat prostration is one of the more frequent results of exposure to unexpected exercise in summer traveling. It is well for tourists to understand the danger of prolonged exposure to the sun in very hot weather. The use of alcoholic stimulants or the drinking of water in excess should be avoided before going out, and the advantages of applications of cold water to the head in these cases should be well understood.

DROWNING.

As the water enters largely into the plans of summer excursionists, the list of summer casualties naturally presents a large number of cases of drowning. While the great majority of these cases are beyond recovery before the body is taken from the water, there are still many in which artificial respiration, persistently and effectively applied, may restore the pulmonary and cardiac action. The Sylvester method is the most popular, consisting—the patient lying upon his back—of alternate contraction and expansion of the chest, by alternately pressing the arms upon the chest and raising them strongly over the head, from twelve to fifteen times a minute, all this of course after the water in the air passages has been emptied by gravitation. The best authorities believe that artificial respiration is often too soon discontinued, and advise that it be persisted in for from thirty minutes to an hour. It should be remembered that the body, until the lungs become filled with water, is buoyant and will float, not high up, but still with its upper surface above the water; and the addition of the merest trifle of assistance, such as is afforded by a small board, not to speak of an oar or larger floating body, will enable the head to be kept well out of the waves. If, then, one can have self-possession in the very disconcerting moment of submersion, he may be able to keep himself afloat until aid can arrive, or possibly until he can reach the shore unaided.

There are many other points in first aid, easily acquired and readily remembered, the application of which may not only contribute greatly to the comfort and ease of the ill and injured, but will also materially assist the practitioner in his future treatment of the case, should the accident require the ultimate action of a physician; but those here mentioned are perhaps of the greatest importance to the summer tourist. The whole subject is an important one, however, and the question of general instruction in connection with it is coming to be recognized as of steadily increasing consequence, while the number of persons qualified to stand in the breach in emergency is constantly growing, all of which is destined to result in a great saving of suffering in future injuries and a vast diminution in the mortality of future accidents.—Medical Record.

A NEW LAW OF HEREDITY.

THE truth of a law of heredity proposed by Mr. Francis Galton has been verified in particular instances, in a memoir* read by him before the Royal Society on June 3.

He first put forward the law, with hesitation, in his book "Natural Inheritance" (Macmillan & Company, 1889), page 134, because it was founded at that time almost wholly upon a priori grounds. Now, being found to hold good in a large group of cases, there is strong reason for its acceptance, as applicable generally to all qualities in all the higher (bisexual) animals. When it is applied to individual cases, minor corrections should, of course, be made in respect to sexual limitations, prepotencies of particular ancestors, and the like.

The law shows the proportion of the heritage that is contributed on the average by each parent, grandparent, great grandparent, and so on. There must be an average contribution, drawn from each ancestral place independently of all the rest, because cases are familiar to observers in which a peculiarity found in some single ancestor has appeared in one or more of the offspring; the present law expresses its amount.

The general considerations upon which the law was originally founded are four in number, but not equally cogent; there is only one solution that satisfies them all. (1) The consequence of limitation in space on particulate germinal matter, which necessitates the loss of one-half of the total germinal material contributed by the two parents. This is confirmed by the commonly (though not universally) accepted fact of observation in the life history of the germ. (2) The remark already made, that any ancestor however remote may contribute his peculiarity independently of the rest. (3) The contribution of the two parents to the child, being analogous to that of the 4 grandparents to the 2 parents, of the 8 great-grandparents to the 4 grandparents, and so on, make it probable that the latent links of the chain of ancestral contributions form a geometric series of terms, diminishing as we proceed from the ancestor downward. (4) The sum of the contributed heritages must be equal to 1.

These four conditions are satisfied by the series $\frac{1}{2} + \frac{1}{4} + \frac{1}{8} + \frac{1}{16} +$ etc. In other words, by the supposition that the two parents contribute between them $\frac{1}{2}$ of the total heritage of the child; the four grandparents, $\frac{1}{4}$; the eight great-grandparents, $\frac{1}{8}$, etc. Or again, that a single parent contributes $\frac{1}{4}$; a single grandparent, $\frac{1}{16}$; and a single ancestor in the nth generation $1/2^{2n}$. A noteworthy consequence of this is that all the 16 great-great-grandparents taken together are no more efficient than a single grandparent, and only one-quarter as efficient as a single parent.

This supposition does not run counter to the commonly accepted view that the true line of descent stretches from germ to germ, and not (except in, perhaps, a small degree) from person to person; the person must on the average be a fair average representative of the germ; consequently statistical averages which are true of the one would be true of the other also.

The verification of the above theory is the object of Mr. Galton's memoir. Appropriate materials for the purpose were at last found in the registered colors of the pedigree stock of Basset hounds. This stock was started some twenty years ago by Sir Everett Millais, who purchased on the Continent 93 selected hounds for the purpose, and has subsequently interbred their most valuable descendants. A Basset Club has long been established, which publishes an occasional stud book (the latest was in 1896) containing the registered name, parentage, date of birth, and breeder of each hound. The colors are not printed in it, but they are always entered on the form sent by the breeders to the club, and Sir E. Millais kindly had them copied for his use. Now there are two, and only two, recognized varieties of these colors: the one technically known as lemon and white (the word "lemon" standing for any shade between yellow and reddish-brown), and the other known as tricolor, from its containing black as well. So there are only two alternative conditions to be considered: "with black" and "without black;" or "tricolor" and "non-tricolor"—say for brevity, T. or N. It is asserted that intermediate and doubtful cases between T. and N. hardly exist.

The result is a collection (1) of 817 hounds of registered colors, T. or N., descended from parents whose colors are also known. (2) Of these, in 567 cases, the colors of all four grandparents are known; again (3) of these, in 188 cases, the colors of all eight great-grandparents are known. These three sets form the material that is tabulated and discussed, and supplies the requisite means for comparing calculated results with observed ones.

There are numerous points dealt with in the memoir, and explained away, of which there is not space to speak of here; one only need be mentioned, namely the question whether either the sire or the dam is so prepotent in transmitting color as to make it necessary to treat the sexes apart. It proves that the dam is prepotent over the sire in this respect, but only in the proportion of 6 to 5; also that the neglect of sex made no sensible difference in a test case. Consequently all ancestral places in the same generation are treated as of equal average efficiency. In short, if n be the order of any given generation (counting n = 1 for parents, = 2 for grandparents, etc.), there are 2^n ancestral places in the nth order, and these contribute between them $1/2^n$ of the total heritage; consequently each ancestral place contributes $1/2^{2n}$ of it. It the same hound fills more than one ancestral place, he has to be rated separately for each of them.

The contributions from the unknown ancestry are reckoned as follows: It was found that 79 per cent. of the parents of T. hounds are T. also, and that 56 per cent. of the parents of N. hounds are T.: consequently the unknown grandparents, great-grandparents, etc., of the T. hounds would have probably $(0{\cdot}79)^2$, $(0{\cdot}79)^3$, etc., of T., and those of the N. hounds would have $(0{\cdot}56)^2$, $(0{\cdot}56)^3$, etc., of T. A simple calculation shows that the sum of the T. contributions to the offspring of the unknown ancestry of each T. grandparent would be 0·0408, and that of each N. grandparent would be 0·0243; these values are used in discussing the set (2). In set (3) the great-grandparents are known, ignorance beginning above that stage; in this case, the pre-ancestral contribution of T. through each T. great-grandparent is found to be 0·0102, and that through each N. great-grandparent is 0·0061. There is no need here to allude to minor corrections, noticed in the memoir, whose effect is too small to be worth regarding.

It thus becomes a very simple matter to determine the contribution from each several known ancestor as well as that from the unknown ancestry of each of them, and, by adding these together, to obtain a coefficient appropriate to any given group of similar cases, such as, when multiplied into the total number of offspring, shall give the "calculated" number that are T.

The test of the truth of the theory lies in the accordance between these calculated numbers and the observed number.

Owing to the large proportion of T. hounds and to selective breeding in favor of T., the different possible matings are by no means equally common, those in which the known ancestry are all (or nearly all) N. being non-existent. The results for such as occurred are summarized below (excluding seven cases, falling into three groups, that lay outside the limits of the table for set 3). The coefficients are added to show the degree of variety in the test conditions. Fuller information is to be found in the tables published in the memoir, out of which these figures are extracted:

CALCULATED AND OBSERVED VALUES COMPARED.

Set 2

Coefficient	·95	·83	·76	·68	·66	·58	·51	·41	·36	·18	—	Total
T. calculated	106	99	21	8	24	92	32	3	5	1	—	391
T. observed	106	100	24	8	20	79	36	4	7	1	—	387

Set 3.

Coefficient	·96	·94	·92	·90	·87	·85	·83	·81	·81	·79	·78	
T. calculated	2	24	13	14	16	18	13	5	8	3	0	(continued)
T. observed	3	25	24	15	17	19	14	6	8	2	3	

Set 3 (continued).

Coefficient	·75	·69	·67	·63	·64	·62	·60	·58	·56	·54	·52	Total
T. calculated	2	1	1	6	4	17	8	18	8	1	7	180
T. observed	2	4	0	5	1	16	11	8	9	1	7	181

Comparing the totals of each of the two sets, we see that the calculated results are practically identical with the observed ones, 391 with 387; 180 with 181; grand total, 571 with 568. There is therefore no constant error, the errors in individual cases balancing one another. When we examine the several groups, 32 in number, which contribute toward the above totals, a remarkable amount of agreement is shown throughout between calculation and observation, such as would raise the art of breeding to a science of considerable precision. The most notable exception is in the sixth column of set 2, where the numbers are 92 and 79, but, as is shown in the memoir, the observed values run there so irregularly with their neighbors that they cannot be accepted as true representatives. The causes of heterogeneity undoubtedly include the disturbing effects of close interbreeding, because particular hounds of good shape that have also considerable prepotency are largely bred from.

The author mentions that he had made experiments with the coefficients, altering them slightly and recalculating, and that he found in every case a notable diminution in the accordance between calculation and observation; the test that the law has successfully undergone thus appears to be even more severe and searching than might have been anticipated.

It is hardly necessary to insist on the value to breeders of a trustworthy law of heredity. Vast sums are spent annually in rearing pedigree stock of the most varied kinds, such as horses, cattle, sheep, pigs, dogs, and other animals, besides flowers and fruits. Certainly no popular view at all resembles that which is put forward and justified in Mr. Galton's memoir, which is epitomized here so far as space admits.—Nature.

* "The average contribution of each several Ancestor to the total Heritage of the Offspring," by Francis Galton, D.C.L., Sc.D., F.R.S.

CLAY INEBRIATES.

IN some sections of the country a number of people are found who daily use clay as an article of food.

It is used so ravenously and with so much relish, and its effects are so marked, that it can be called a veritable inebriety. The clay eaten is of dirty white color, and has a particular oily appearance and does not crumble, but becomes sticky when moistened. It is held in the mouth until it dissolves, and is swallowed in small quantities. It evidently possesses some nourishment, and the opinion prevails that persons can subsist on it for days without any other food. The

quantity used varies largely from two ounces to several pounds a day.

There is a strange fascination which, like the diseased craving for narcotics, demands so much of this clay every day.

When, by accident or design, the supply is cut off great restlessness, anxiety, and intense depression follow. The effect of clay eating is noted on young persons by blanching the skin, giving it a peculiar pallor, and soon a prematurely old, wrinkled look. The mind seems to be depressed and under a cloud, and all vivacity and emotionalism reduced to a low level.

General muscular indisposition to exertion and indifference as to the consequence of acts and the possibilities of the future are the symptoms in adult clay-eaters. Whisky drinking, tobacco smoking, chewing, dipping, and snuffing are common accompaniments.

All ambition to improve their surroundings and add to the mental pleasures of life is absent, and profound general depression prevails. Superstitious hallucinations and fears of the supernatural, with efforts to interpret every unusual event in nature, and the most primitive struggles to supply the common wants of the body, constitute the whole of life.

Very little sickness follows, and after years of this addiction some acute disease of the stomach or liver is followed by death.

These people occupy some of the mountain counties

POWER ON LAND.

POWER AT SEA.

SCULPTURED FOUNTAINS AT THE HOFBURG, VIENNA.

of the Southern States, and seem satisfied to live in the poorest sections of the country. They are content to live isolated, and by farming, hunting, and fishing make a living.

The craze for the clay used is remarkable for its persistence and tenacity. The supply for daily use is provided with more energy and precision than food.

The skin of clay inebriates soon becomes of a dirty yellow color, and never changes during life. Tobacco using seems to be more closely associated with this addiction than spirit drinking. No change ever takes place except death. They cling to the same ways of life and living, never increasing the amount of clay used to any extent from one generation to the other. Both body and mind slowly retrograde down through degrees of dementia to death.—Quarterly Journal of Inebriety.

THE FOUNTAINS AT THE HOFBURG IN VIENNA.

Two magnificent sculptures were recently unveiled in Vienna (Austria). The façade of the Hofburg there has been restored, and, as of old, forms a semicircle bounded on either side by beautifully crowned wings. At this place the two fountains are raised, bringing out with great force and beauty the originality of the ancient architecture. They bear their white figures on a ground of dark brown marble and represent, respectively "Power at Sea" and "Power on Land."

On the right hand side of the semicircle is the fountain whose figures represent in their powerful allegory "Power on Land." This work of art was designed by Hellmer. The mass of the monument rises artistically in a triangle, at the vertex of which a youth, the type of power, stepping forth from the niche, drives back the powers which threaten from below. One monster, clutching the flowers that adorn the throne, in terror shrinks back, and looks with awe on the conqueror. The second demon falls headlong from the rock, while another makes vain attempts to unbalance the rocks, which, piled up, support the ruler. An eagle with extended wings defends the throne, heedless of the serpent, which is the symbol of treachery, creeping up the rock.

Edmund Hellmer has hitherto shown a liking for the antique, and has dealt largely with wild scenes, as we find them in the beautiful figures and inspired groups of the monument in memory of the rescue of Vienna from the Turks. It would scarcely have been thought that he would render with such clearness the expression of Titanic force. Whoever knows the lightly draped garments on Hellmer's splendid monument, its resplendent armors of the time of the Turks, its heroes of the rescue, scarcely imagines that the hand which carved so bright and lovely a scene could represent crude force in a composition which would fit so aptly with that of Weyr, the artist by whose hand the other fountain was fashioned, and who is accustomed to the treating of such themes. It is clear that he has even surpassed his former productions by this work, and though he is not so full of variety and so picturesque as Weyr, yet he knows how to shape his sculpture uniformly, forcibly, and so as to carry its meaning well. Not quite up to Weyr's level is the statue of the youth.

Though full of the nobility of his character and distinctly great in the expression of his face, the silhouette of this Apollinic figure is not without some faults. Yet it aptly crowns the interesting group which must be reckoned among the most deserving productions of art in our times.

Edmund Hellmer was born at Vienna in 1850, and obtained a government prize as pupil at the academy there. He is now professor at that institution. Nearly all young sculptors of Vienna have passed through his school, or have attended it before going to foreign colleges. Johann Tadrusz, the designer of the "Maria Theresa" monument, and Th. F. Ries, a young Russian sculptress, have lately made their names known in all lands as pupils of Edmund Hellmer.

The other fountain, as we have said, represents "Power at Sea" and is the work of Weyr. A master in decorative plastic art, he has for the first time used his great talent in the service of that artistic effect which must be studied closely, intelligently and into the smallest detail. His productions have so often come to public notice as flowing silhouettes on the gables of buildings that there was naturally some wondering expectation to see how he would fashion these groups, that might as it were be touched, who had hitherto shown such remarkable ability in calculating his playful lines for splendid distance effect. He has solved the problem in a truly wonderful way. The architectural motives, the muscular body of ancient Neptune, who, the trident in his right, looks with amazement on the genius, half man, half fish, falling over the rocks, and the artistically effective Moloch, are grouped in powerful unison beneath the queenly figure which crowns the group. This sculpture, a "Power at Sea," occupies the left niche in the façade. The momentous motion of the combined impressions of this masterpiece, the right side of which, with the fallen demon, is wonderfully conceived, is extremely pleasing to the eye, and gives testimony of virtuose ability in the composer.

The idea of impotent power could not better be depicted than by this work. Technically of great merit are the torso of Neptune and the breast of the crowning figure; a very modern criticism might, however, find fault with the somewhat conventional attitude of arms and legs. In this work Professor Rudolf Weyr has presented his best efforts, and the result is so great that it surpasses the production of most of the Vienna artists.

Weyr was born in 1847, was pupil of the Vienna academy, is known specially for his frieze the "Bacchantes" in the new Burg Theater, the excellent bas reliefs on the "Grillparzer" monument, and for numberless tomb sculptures.

His reputation made him well worthy to add to the plastic decorations of the great Austrian capital.

We are indebted for the views of these fine specimens of the plastic art to the German paper Ueber Land und Meer.

DOES TRACK SWEEPING PAY?

WE venture the opinion that, if more managers would look carefully into the matter of clean tracks versus dirty tracks and the cost of sweeping versus the cost of power, sweepers would be used more liberally than they are now, or at least more track brushes would be used, says the Street Railway Review. Since street railways must be operated in all kinds of streets and since municipal management often decrees that streets must remain dirty for want of street cleaning funds, the only loophole of escape for the manager is to clean his portion of the street himself. The question then arises as to how much sweeping and cleaning is justified by the return therefor in dollars and cents. One concrete example will give some idea of the economy of running a sweeper over tracks once a day, where there is moderately heavy traffic. A double track route 5 miles long, running cars at 5 minutes' headway, at 8 miles per hour for 10 hours of the day, and cars at 10 minutes' headway 10 miles per hour for 8 hours of the day, will require 15 cars during 10 hours and 6 cars for 8 hours of the day. The total mileage during the 5 minutes' headway hours is equal to the 15 cars in service multiplied by 8 miles per hour multiplied by 10 hours, or 1,200 car miles. Adding to this the mileage made by six cars running 10 miles an hour for 8 hours, or 480 car miles, the total daily mileage will be 1,680. Assuming that power costs 1 cent per car mile with a clean track and

the power to run that route costs $16.80 per day, a dirty track may easily make this 20 per cent. more, making the amount to be charged to dirty track $3.26. To run a sweeper once over that route each day would take the time of two men for about one hour, making cost of labor about 40 cents, and allowing 8 cents per mile for power to run the sweeper, we have 30 cents more, or a cost of 70 cents per day to run the sweeper once over that one route to save $3.26. This, of course, does not include sweeper maintenance, but neither does the other calculation include car wheel, track and motor maintenance. The amount saved relative to the cost of sweeping decreases as the traffic gets lighter, but there is a considerable margin of economy in favor of the sweeper, even allowing for a considerable decrease of traffic. Besides this, there are track brushes to fall back on in case it does not pay to run a sweeper, and in many cases sufficient sweeping can be done by a special attachment to one or two cars.

THE BRITISH BATTLESHIP RENOWN.

THE recent naval review at Spithead brought together the most interesting types of war vessels, both British and foreign. The vessel which we illustrate is her Majesty's first-class battleship Renown, 12,350 tons. It was built at Pembroke Dock Yard, from the designs of Sir W. H. White. She is in many respects similar to the Prince George, which we have already described. For our engraving we are indebted to The Engineer and for our description to Brassey's Naval Annual. The Renown was laid down in Pembroke Dock Yard in February, 1893, and was launched in May, 1895. As already stated, she is 12,350 tons displacement, and her estimated speed, with 12,000 horse power, was 18 knots. The machinery of the Renown is by Messrs. Maudsley, Sons & Field. Great interest was attached to the trials of the Renown, as she was expected to prove herself the fastest battleship afloat. This she has succeeded in doing by a very narrow margin over the Victorious, but the latter was tried at considerably less than her load draught. At the trial it was found that for a period of eight hours under natural draught the engines made 97·8 mean revolutions; the mean indicated horse power was 10,708; her speed was 17·9 knots. Under four hours' forced draught the mean number of revolutions was 104·5, the mean indicated horse power was 12,901, the speed was 18·75 knots. On the thirty hours' coal consumption trial the mean draught was 26¾ feet and the mean speed 15·3 knots with 6,189 horse power and 86·9 revolutions. The consumption of coal was 1·88 pounds per I. H. P. per hour. The Renown is protected on the same principle as the Majestic class. The thickness of the barbette armor is 10 inches as compared with 14 inches, and of the side armor 8 inches and 6 inches as compared with 9 inches throughout. The main armament consists of four 10 inch guns as compared with four 12 inch guns. All the 6 inch quick fire guns are mounted in casemates, but only ten are carried instead of twelve. On the gunnery trials the 10 inch barbette guns were fired thirty degrees before or abaft the beam, as the case might be; they were also fired simultaneously directly fore and aft with full charges and at 35 degrees elevation without injuring the ship or the mountings.

The cost of the Renown was about $2,750,000.

HER MAJESTY'S FIRST-CLASS BATTLESHIP RENOWN, 12,350 TONS, CONSTRUCTED AT PEMBROKE DOCK YARD.

The first direct mail connection across the Sahara has lately been completed. It runs from Senegal via Timbuctoo to the north.—Uhland's Wochenschrift.

TOWNS' WATER SUPPLY AND ITS DISTRIBUTION.*

By W. M. WATSON, Toronto.

IT is a crime to supply a town with tainted water or compel those living in villages to depend on wells of doubtful purity, which sometimes run dry when water is most in demand. Abundance of good water in the house convenient for use at will is a sanitary necessity, and it is the duty of the governing body to arrange for and secure a permanent supply at a reasonable expense and charge to the consumer.

When constructing waterworks, care should be taken in arranging and joining the iron street mains and conduits and every other apparatus used for distributing or conveying the water, so that they cannot be injured by frost or dirt or by the pounding of water hammer caused by sudden concussions of confined air. The joints should be well and carefully made, and if lead be used, each joint should be run full and solid at one teeming of the ladle, at least to a depth of two inches. Maiden or new pig lead should always be used for jointing. Each joint should have two circles of hemp rope driven well back and tight for the lead to wedge against. It is the hemp rope that keeps the joint tight; the lead holds it to its place, so it is necessary to have a good quality of rope. Above all else, it is necessary to make proper provision for cleaning out every part of the pipe system and to prevent waste or leakages, which not only wastes money, but damages the roadbeds and the foundations of property adjoining the line of pipes.

Water suitable for domestic use should be transparent, without smell, taste or suspended matters, totally free from any excreta or sewage deposits of any kind. Marsh or nullah water, which is loaded with vegetable débris, must be carefully avoided. Water for industrial purposes should be void of minerals, because they increase the cost of soap and scouring materials when used for cleaning purposes; they scale steam boilers and heating pipes and interfere with the production of colors when dyeing fabrics. The French cloths are always softer to the touch than British, because of the quality of water used in finishing and dyeing, and thousands of pieces of manufactured stuffs are sent over to France from England to be dyed and finished and then returned. Tainted, dirty water, with a mixture of fine sand, would ruin a stuff manufacturer or dyer in a short time. It is advantageous to secure water well aerated, similar to the water at the foot of Niagara Falls or rain water, which, during its fall through the atmosphere, secures (according to analysis made by Dr. E. A. Parks, F.R.S.) a large percentage of oxygen.

D. G. F. Gaskins, C.E., when delivering his presidential address before the British Association of Waterworks Engineers, at Nottingham, last year, stated that to manage a waterworks a knowledge was demanded which could only be obtained by close study, application and practice. This is different teaching to that of a prominent civil engineer, who wrote to me saying that there was no room in Canada for experienced waterworks superintendents, because the colleges were turning out yearly more students than there were such places to fill. If the students fill such positions raw from the colleges without learning the trade and securing working experience, whatever salary or wages they receive, it is little better than robbery of the ratepayers. A valuable engineer never attempts to construct or even manage the construction of systems that have been planned and laid out from his own ideas. He keeps his position and expects the mechanic and manager to faithfully keep theirs.

Mr. Mansergh, in his fifteen thousand dollar report on Toronto waterworks, expressed himself in a way that can only be interpreted to mean that he considered the construction and management of all American waterworks systems of a low standard. He attributed the reason to the fact that the city of Toronto had to pump over one hundred gallons of water for each inhabitant each day, to waste or misuse, adding the important remark, "as in other American cities." The reason why there is a low standard of public works in this country in comparison to the works in the old country is because there is no proper check placed on the local authorities by the government. A single ratepayer, having a substantial grievance and who can prove that the local authorities are wasting public money, or mismanaging the public business, or allowing the public works to be mismanaged, or voting themselves funds, etc., can petition the English local government board, who will send an expert engineer to make a full inquiry, and if abuse of the trust put in the representatives elected by the popular vote be proved, or it is found that any of the officials are not worthy of the confidence placed in them, he will report the same to the government, who will take measures to correct the evil.

I was appointed to investigate a waterworks on which there had been an inquiry of this kind, and I proved that most of the wealthiest manufacturers were daily stealing large amounts of water, and that less than half the amount of water provided by the ratepayers of the town was paid or accounted for. The result of the government interference in this case was a saving to the public taxes of about $30,000 each year afterward.

Mr. Griffith, C.E., states that under proper management the advantages of local authorities owning their own waterworks are as follows:

1. A local authority elected by residents in the districts has a greater personal interest in the matter of supply, and is better qualified to administer the undertaking in their own interest than a private company, whose only object is profits.

2. A local authority need not make any profit out of the supply. They can also borrow capital for construction of the works cheaper than a private firm, and reduce the charges for supply to consumers accordingly.

3. Public sentiment is always in favor of having such a universal necessary of life and health in their own hands.

The chief difficulties against public ownership are:

1. The periodical changes of council and sometimes even the constitution, which often interferes with the continuity of a policy.

2. The liability of the works being handled by men appointed through society, family or political influences, in place of having skilled mechanics and experts.

3. The habit, which is sometimes allowed or blindly ignored, of selling favors and accepting perquisites, which often is the cause of scamp work being done, and of public works costing more than similar works done by private business firms or such well conducted councils as Glasgow.

The revenue from the sale of water in Toronto is stated in the newspapers to be $445,000. Taking the population at the highest stated number, viz., 190,000, it runs about $2.30 per head, an average for each house of five inmates of $11.50. They say we owe on account of the waterworks $3,817,287.32, or an average per head

* Abstract of paper in Canadian Engineer.

of $20.09. Had the Toronto waterworks been constructed and managed by a business firm, with the ability of the T. Eaton Company, for example, it would not have cost half, and the charge to consumers could have been proportionally less.

There cannot be a great difference between the need for water in European and Canadian towns which have similar conditions, only that English towns use a great percentage of their water in supplying cheap public swimming baths of large dimensions. The difference in consumption has no connection with the fact that the heat or cold is more excessive, because the returns given us of the water pumped in Toronto in the months of April and November, when there is no garden or street watering, public water fountains, no frost needing taps to be kept running, nor anything at all different to any British town, gives only a little different figures to those published for any of the other ten months.

Mr. Palmer, C.E., states that the Malvern authorities supply each water consumer with a meter, and the average consumption is 5½ gallons per head per day. I know several small towns that do not use meters which use less than 6 gallons of water for household purposes per head per day. The total quantity of water used for all purposes in the town of Nottingham, with a population of 230,843, last year was stated to be under 21¾ gallons per head per day. In Bradford, a town of 240,000 inhabitants, they used 26 gallons per head through meter for manufacturing purposes and about 27 for all other purposes, including several large swimming baths. Mr. Bateman states that he tested a group of 14 towns in England and found the average consumption for all purposes was 24 gallons, and in a single group of working class houses containing 82 inmates the average consumption per day per head was 7½ gallons. I myself tested a house in Toronto by having a new Siemens water meter fixed on for five years. The house had 11 inmates, 2 baths, 1 basin, w. c., hot water and range boilers, hose pipe, stable and horse. The average amount of water taken each year was under 28,000 gallons, less than 7 gallons per head per day.

The Toronto Star on May 1 stated that only 198,000,000 gallons of water were sold to manufacturers in a year in Toronto, or under 3 gallons per head, leaving about 100 gallons per head per day for sanitary and domestic consumption, or 75 gallons over the consumption of similar British towns. If Toronto were situated in England, there would be a government inquiry into the cause of this waste. Returning again to the mechanical and engineering side of the subject, as I have before stated, the best water for public use is rain water collected from clean land, because it cannot possibly be contaminated by mineral, manurial or sewage deposits. Taking a supply from a river near its source or from an elevated lake is often as good as collecting rain water.

When taken from a river, the mouth of the suction pipe should face the way the water flows, because by so doing the best water will be drawn in, while the floating impurities will pass forward with the current. When from a lake, it should face downward for the same reasons. Taking water from a lower level than the town is built on is often injudicious, because it may be fouled by the sewage from the population living within the watershed, which sometimes contains an area of several thousand square miles, and should the population be small at present and the impurities from the sewage imperceptible, it may soon alter. All large towns should have forethought sufficient to arrange for a good permanent supply while the opportunity serves. To depend on a supply by pumping and long suction conduits is risky and expensive, and it is probably cheaper to carry a supply fifty miles and have a proper gravitation system:

1. Because the source of supply being necessarily at a higher elevation than a pumping source, it is less liable to be contaminated.

2. Though the first cost of works may be more on account of the long length of trunk mains, which might have to be conveyed through tunnels and across ravines on viaducts, yet the annual expenses of pumping, in wages, repairs, renewals, etc., will probably amount to more than would pay the interest on the capital expended on a comprehensive, well engineered scheme. Such a plant would be safe and permanent, besides free from contamination, because by making judicious arrangements to supply the villages located on the route of the pipe by measure, sufficient revenue might be collected to pay the interest on the cost of running the trunk pipe through their section of territory.

When it is necessary to store water in reservoirs so that the supply can be abundant when the rainfall is least, such reservoirs should be carefully covered over and ventilated. In form they should be deep rather than extended, so as to lessen the evaporation, to keep the water cool and at an even temperature so far as possible all the year round, to prevent the water from absorbing the impure gases from the atmosphere and prevent the sun's rays from increasing the microbes and bacteria. When large natural reservoirs are made in the hills, they must necessarily be open, and the face of the water exposed to the sun and air; such water should be passed through a good clean filter immediately before entering the supply pipes. In fact, all water, however collected and stored, should be filtered.

It is a fact that the purer and softer the water is, the easier it is to contaminate. It will attract and absorb minerals and poisonous gases with a wolfish appetite. At Harrogate, in England, there are eleven springs of water, each loaded with different minerals and chemicals, which each stream has taken up on its passage through the earth from the seat of the rainfall to the springs.

Then another example: Six families, living in good, airy, isolated houses, went on their holidays for a few weeks to the seaside. A short time after each family returned home some of its members were taken ill with typhoid fever. Being superintendent of the water supply, it was my duty to investigate so remarkable an occurrence, and I found that the owner had broken the laws of water distribution by allowing his tenants to take the whole of their water supply from a large shallow open cistern, hidden in the false roof, that was open from end to end over all the sleeping rooms of the six houses, and that the loft had no ventilation whatsoever; so that all the poison contained in the atmosphere of the sleeping rooms passed through the porous plastered ceiling, and having no other means of escape was absorbed by the sheet of water in the cistern, and the water became poisoned before being used by the inmates. A French writer has, indeed, proved that the human system can be trained to receive large doses of poison without serious injury. If his theory was incorrect, how could so many people live in a poisoned atmosphere, yet have general good health. The trouble with this group of families was that they had lived at another place for a time and broken the continuity of the doses, and when they returned home and began to take them up again on a healthy, well ordered constitution, the sudden start upset them. The water would be worse than usual on account of a small quantity only having been used during the time of absence. I have related this at length to show the great importance of covering fresh water tanks and reservoirs, and the advisability of erecting them in places sufficiently removed from any chance of contamination.

With the object of removing dirt from the lower points of street water mains, some engineers connect the ends of the pipes together and form a circuit of water down one street and up another. The method does not remove the evil, but distributes over a larger area the dirt or polluted water in the pipes. I believe the circulating policy is adopted in Toronto, for I am sometimes engaged to remove fish and other obstructions from taps and valves. I also notice if a bath full of fresh water stands for a few days, there is a sediment at the bottom. Then water taps and other waterworks appliances only keep in good condition about a quarter as long as at places where the water is free from fine sand and grit. The cost of repairs and renewals on account of fittings being injured by the grit must amount to a large sum throughout the whole city. I once witnessed water flowing from a branch pipe from which a fire hydrant had been removed run black for about fifteen minutes, leaving a large quantity of gritty deposits on the ground, and at another time a six inch water main that had been taken out on account of a defect had about one inch of black and green sludge adhering to the lower side.

The dirt could not lie in that position, nor the water get so far polluted as to run dirt for so long a time, if reasonable provision were made to clean out the pipes and suction conduit, and the conduit were laid in such a mechanical way that the joints could be kept permanently watertight. The proper way, in my opinion, to lay down distribution water mains for a town is to lay the large carrying mains along the roads having the highest elevation, and take out branches commencing with a cut-off valve and air ball, then continue them down along the streets to the lowest points of each street or section of streets, and on the terminating end of each branch pipe affix a full sized sluice valve about ten yards beyond the last service pipe. Round the sluice valve build a well or valve chamber with a gully trap and drain pipe twice as large as the water pipe, and construct the bottom one foot below the valve. Solids and impurities of all kinds contained in water mains that are under pressure are always forced to the lowest points, and can be easily removed by opening the terminating valves about once a month, or oftener, according to the quality of the water, for about one half minute.

Water mains should be as carefully graded as gas or sewer pipes, and have air balls of the self-acting kind fixed at all the highest points, and full sized sluice valves at all the lowest points and dips, so that the whole system may be emptied and cleaned when necessary, and freed from deposits of grit and slime.

It must be remembered that water will run through water without moving the water adhering to the sides of the pipe it is passing through, and if the mains are larger than is needed to pass the supply taken from them, and the water is soft and pure, the motionless water clinging to the sides will set up an action with the metal and become hardened and turn into a brown calcareous matter, and continue to grow and diminish the bore of the pipe until there is just sufficient room to pass the necessary stream, when it will stop and continue in that shape for any length of time. For example, I inspected a fire hydrant intended to protect an isolated hall in a corner of a town, and found that it would not deliver any more water than the common bib water tap on the kitchen sink. On cutting the three inch main to find the cause, I found it calcarized and the bore reduced as above stated, and the whole of that branch line for about one-half mile had to be relaid with new pipes. Had the terminating sluice valve been open full wide once a month, and the dead water clinging to the sides of the pipe let out, along with any calcareous scales that might have started to form, it would never have been necessary to relay, and the hall would not have been in jeopardy for several years.

A 30 inch earthen pipe having cemented joints, that carried water from one storage reservoir to another on the moor land, got its bore diminished by fine rootlets passing through the cracks in the cement joints, growing inside and choking the interior. The calcareous matter growing on the inside of water mains can be removed by a machine called a ferret, which is so constructed that the pressure of water turned on behind it will force it through a moderate length of water pipe, and during its passage it will scrape the inside clean. When this method is used, clean out doors must be provided at short intervals.

Neither large nor small water filters are of any use except proper provision is made for cleaning them easily, because, no matter what material is used for a filtrate, there is a limit to its usefulness. The best filters are made from animal charcoal well pressed together, so that the water must pass through the coal or magnetic carbide of iron. For purifying fresh water that is void of sewage deposits, about fifteen inches of fine washed, clean, sharp sand and twenty inches of gravel will make a suitable filter, if the top layer is removed and clean washed; then spread on again about once each week. This will make the water of a bright color and pure. If I were to build a filter on a large scale I should have a graded concrete bottom, so that the water on escaping from the filtrate material would come together and form a stream to enter the distribution pipes. I would then have a false grated bottom, bearing on pillars, to hold the filtrate material. I would run the water to be treated over shallow troughs, the bottoms pierced with very fine holes, at a convenient elevation above the filter, so that all the water intended to be filtered would fall into the filter in a fine spray similar to a needle bath; falling a distance, say, of four feet, in the form of a fine spray, the water would be aerated. I would also make a good system of ventilation that would insure a strong current of air to be continually passing between the cemented and false grating floor at the bottom of the filter. The water should pass slowly through at a pressure of about two feet above the face of the sand.

When water is delivered to consumers the shut off tap, usually fixed in the sidewalk near the street line, should be of the screwdown pattern, with the valve working loose inside, so that when full open it would allow water to pass through toward the house, but it would not allow any to return back into the mains. The tap would have a double action; it would not only make a first class stop tap, but also a foot or check valve. This would prevent any fluid being forced or drawn into the street mains, and effectually prevent the return of hot and tainted water from water heating boilers, steam and range boilers, etc., which is at present very prevalent.

Lead water pipes when laid in the earth should not be near any metal, because a galvanic action will be produced; nor near an electric car line, for the electricity will damage the lead if the soil it lies in is damp and a good electric conductor. Nor should it be laid near any tile or other drain, because a leakage of water would find a downward way of escape, and could not be easily found; nor under any manure pile, or near dirt or filth of any kind, because when the water is motionless in the pipe it will absorb some of the foul gas thrown off from such filth through the lead coating, and become tainted. Lead is the handiest metal for small water pipes, because it can be easily bent to any angle. When damaged by frost or water hammer it is easy to repair without removal. When laid underground it will sink with the soil, stretch, or give and take a little without injury. On the other hand, when rigid iron is used it will break before bending, and if damaged a full length has to come out. It is very unfortunate that a chemical action sets up between pure soft water and lead, which poisons the water when it stands motionless in the pipe for a few hours, and thousands have been seriously injured in health by drinking and cooking with water poisoned in that way.

The water that poisoned the Louis Philip family, of Claremont, contained seven-sixteenths of a grain of lead per gallon, and the water taken from the same source had injured to various degrees thirty-four per cent. of the population of the town. Analysts differ as to whether water can be poisoned by passing through galvanized or zinc pipes or not. I am positive that distilled water can be injured by using galvanized vessels, and, if so, other water must be injured to a less degree. Black iron, specially made very strong and soft in nature, so that it can be bent easily, is the healthiest article for use for service pipes. Some of the means suggested for removing the evil and still using lead pipes for domestic water supply, are: 1. To line the lead pipe one-sixteenth of an inch thick with block tin. 2. To give the pipes a bituminous coating. 3. To boil the lead pipe before using in a strong solution of sulphur and soda.

THE WORKING OF SHEET ALUMINUM.

Now that the manufacturers of aluminum have reduced the price to such an extent that aluminum used in large quantities for replacing brass can be used as economically as this latter metal, it has occasioned a great many inquiries as to what the proper methods are for working it, both rapidly and economically. Some factories have maintained that although the relative price of aluminum and brass were the same, after taking into consideration the specific gravity of the two metals, it was impossible to work aluminum as cheaply as brass could be worked, for the reason that the machinery working the metal could not be operated as fast, etc. Anyone, however, who has gone carefully into this subject will find that this is not so, and that when it comes to performing machine work of any kind on the sheet metal, it can be done in all cases as cheaply as brass, German silver, or tin plate can be worked, and in some instances it can be worked cheaper.

It has often been said, and correctly so, that the alloys of aluminum compare with the pure metal about as brass compares with copper. No better illustration could be given than this, and so accustomed have many of the shops in this country become to working brass that they would find it difficult to work copper, but the majority of cases in aluminum are just the reverse; that is, the people who find fault in regard to the cost of working aluminum have in the majority of instances based their opinion on the cost of working the pure metal. And so it is in the manufacture of most of the fancy articles out of aluminum; it is no more advisable to use the pure aluminum than it would be to make a similar article ordinarily made of brass out of the pure copper. This fact is not fully appreciated, especially by the people using aluminum, because their first experience has been with the pure metal, and it is difficult to get them to make a change.

The great secret, if there is any, in working aluminum, either pure or alloyed, consists in the proper lubricant and the shape of the tool. Another great disadvantage in the proper working of the metal is that, when a manufacturer desires to make up an article, he will procure the pure metal in order to make his samples which, of course, is harder to work than the alloy. But the different grades of aluminum sheet which are on the market are so numerous for different classes of work that it might be advisable to consider them for a moment before passing to the method of working them.

The pure metal, to begin with, can be purchased of all degrees of hardness, from the annealed, or what is known as the "dead soft" stock, to the pure aluminum hard rolled. Then comes a harder grade of alloys, running from "dead soft" metal, which will draw up hard, to the same metal hard rolled; and still again, another set of alloys which, perhaps, are a little harder still when hard rolled, and will, when starting with the "dead soft," spin up into a utensil which, when fin-

ished, will probably be as stiff as brass. These latter alloys are finding a large sale for replacing brass used in all classes of manufactured articles.

To start with lathe work on aluminum, probably more difficulty has been found here, especially in working pure metal, and more complaints are heard from this source than from any other. As stated before, however, these difficulties can all be readily overcome if the proper tools and the proper lubricants are used, as automatic screw machines are now made so that they can be operated when working aluminum just as readily as when they are working brass, and in some cases more readily. To start with the question of the tool, this should be made as what is known as a "shearing tool," that is, instead of a short, stubby point, such as would be used in turning brass, the point should be lengthened out and a lot of clearance provided on the inside of the tool, so as to give the chips of the metal a good chance to free themselves and not cause a clogging around the point of the tool. A similar tool, for instance, as would be used for turning wood.

The best lubricant to be used would be coal oil or water, and plenty of it. The latter is almost as good as coal oil if enough of it is used, and with either of these lubricants and a tool properly made, there should be no difficulty whatsoever in the rapid working of aluminum, either on the lathe or on automatic screw machines.

To go from the lathe to the drawing press, the same tools here would be used in drawing up shapes of aluminum as are used for drawing up brass or other metals. The only precaution necessary in this instance being to use a proper lubricant, which in this case is a cheap grade of vaseline, or in some cases lard oil, but in the majority of instances better results will be derived by the use of vaseline. Aluminum is probably susceptible of deeper drawing with less occasion to anneal than any of the other commercial metals. It requires but one-third or one-fourth of as much annealing as brass or copper. When, for instance, an article which is now manufactured in brass, requiring say three or four operations before the article is finished, it would probably have to be annealed after every operation. With aluminum, however, if the proper grade is used, it is generally possible to perform these three operations without annealing the metal at all, and at the same time to produce a finished article which to all intents and purposes is as stiff as an article made of sheet brass.

Too much stress cannot be laid on the fact of starting with the proper grade of metal, for either through ignorance or by not observing this point is the foundation of the majority of the complaints that aluminum "has been tried and found wanting." If, however, it should be found necessary to anneal aluminum, this can be readily accomplished by heating it in an ordinary muffle, being careful that the temperature shall not be too high—about 650° or 700° F. The best test as to when the metal has reached the proper temperature is to take a soft pine stick and draw it across the metal. If it chars the stick and leaves a black mark on the metal, it is sufficiently annealed and is in a proper condition to proceed with further operation.

Next taking up the question of spinning aluminum, again success depends particularly on starting with the proper metal. The most satisfactory speed for articles from five inches to eight inches in diameter is about 2,600 revolutions a minute, and for larger or smaller diameters the speed should be so regulated as to give the same velocity at the circumference. Aluminum is a very easy metal to spin and no difficulty should be found at all in spinning the proper grades of sheet. Several factories that are using large quantities of aluminum now, both for spinning and stamping, are paying their men by the piece the same amount as they formerly paid on brass and tin work, and it is stated that the men working on this basis make anywhere from 10 per cent. to 20 per cent. more wages by working aluminum.

After aluminum has been manufactured into the shape of an article the next process is the finishing of it. The best polish can be obtained by first cutting down the metal with an ordinary rag buff on which use tripoli, and then finish it with a dry red rouge which comes in the lump form, or that which is known as "White Diamond Rouge." One point, however, that it is necessary to carefully observe is that both the tripoli and the rouge should be procured ground as fine as it is possible to grind them; for, if this is not done, the metal will have little fine scratches all over it, and will not appear as bright and as handsome as it otherwise would.

If it is desired to put on a frosted appearance, this can either be done by scratch brushing or sand blasting. A brass wire scratch brush, made of crimped wire of No. 32 to No. 36 B. & S. gage, with three or four rows of bristles, will probably give the best results. This work of scratch brushing can be somewhat lessened, however, if, before applying the scratch brush to the surface of the aluminum, the article is first cut down by the use of a porpoise hide wheel and fine Connecticut sand, placing the sand between the surface of the aluminum and the wheel, so that the skin and the irregularities on the surface are removed, and then putting the article on a buffing wheel before attempting to scratch brush it. This method, however, is probably more advantageous in the treating of aluminum castings than for articles manufactured out of the sheet metal, as in the majority of cases it is simply necessary before scratch brushing to cut down the article with tripoli, and then polish it with rouge as already described, before putting on the scratch brush; in this way the brush seems to take hold quicker and better, and to produce a more uniform polish.

An effect similar to the scratch brush finish can be got by sand blasting, and by first sand blasting and then scratch brushing the sheets, a good finish is obtained with very much less labor than by scratch brushing alone. Another very pretty frosted effect is procured by first sand blasting and then treated as hereinafter described by "dipping" and "frosting," and many variations in the finish of aluminum can be got by varying the treatment, either by cutting down with tripoli and polishing, scratch brushing, sand blasting, dipping and frosting and by combinations of those treatments. A very pretty mottled effect is secured on aluminum by first polishing and then scratch brushing and then holding the aluminum against a soft pine wheel, run at a high rate of speed on a lathe, and by careful manipulation quite regular forms of a mottled appearance can be obtained.

The dipping and frosting of aluminum sheet is probably the cheapest way of producing a nice finish. First remove all grease and dirt from the article by dipping in benzine, then dip into water in order that the benzine that adheres to the article may be removed, so as not to affect the strength of the solution into which it is next dipped. After they have been taken out of the water and well shaken, the articles should be dipped in a strong solution of caustic soda or caustic potash, and left there a sufficient length of time until the aluminum starts to turn black. Then they should be removed, dipped in water again, and then into a solution of concentrated nitric and sulphuric acid, composed of twenty-four parts of nitric acid to one part of sulphuric acid. After being removed, the article should be washed thoroughly in water and dried in hot sawdust in the usual way. This finish can also be varied somewhat by making the solution of caustic soda of varying degrees of strength, or by adding a small amount of common salt to the solution.

In burnishing the metal use a bloodstone or a steel burnisher. In burnishing use a mixture of melted vaseline and coal oil, or a solution composed of two tablespoonfuls of ground borax dissolved in about a quart of hot water, with a few drops of ammonia added. In engraving, which adds materially to the appearance of finished castings, book covers, picture frames and similar articles made of sheet, probably the best lubricant to use on an engraver's tool in order to obtain a clean cut, which is bright, is naphtha or coal oil, or a mixture of coal oil and vaseline. The naphtha, however, is preferred, owing to the fact that it does not destroy the satin finish in the neighborhood of the cut, as the other lubricants are very apt to do. There is, however, as much skill required in using and making a tool in order to give a bright, clean cut as there is in the choice of the lubricant to be used. The tool should be made somewhat on the same plan as the lathe tools already outlined. That is, they should be brought to a sharp point and be "cut back" rather far, so as to give plenty of clearance.

There has been one class of work in aluminum that has been developed lately and only to a certain extent, in which there are great possibilities, and that is in drop forging the metal. Recently some very superior bicycle parts have been manufactured by drop forging. This can be accomplished probably more readily with aluminum than with other metals, for the reason that it is not necessary with all the alloys to work them hot; consequently they can be worked and handled more rapidly.—The Aluminum World.

THE MANUFACTURE OF RUBBER SUBSTITUTES.

SUBSTITUTES enter very largely into the compounding of rubber, because of certain distinct advantages which they possess and which are not shared by coal tar or the simple mineral adulterants. They have not the vulcanizing effect of sulphur or the metallic oxides and sulphides. Their chief value lies in cheapening the stock without disturbing its working qualities or impairing the texture, finish or weight of the manufactured product. Their after effect on the life of the goods is, however, another matter.

The term rubber substitute may be broadly considered as including any substance possessing characteristics similar to those of unvulcanized rubber and adapted to displace it in compounding. Ordinary reclaimed rubber, as well as the sulphurized oils, are included in this definition.

The reclaimed rubber of commerce is obtained by steaming or devulcanizing old rubber waste, generally shoes, freed more or less perfectly from fiber. Having originally contained some real caoutchouc, it is generally considered rubber of low grade rather than rubber substitute. Since its introduction its use has rapidly extended, until it is now a very essential factor in the ordinary and cheap lines of goods and its presence is not entirely unknown even in the highest grades. As a substitute it ranks first in merit and general use; the annual output in this country alone reaching thousands of tons.

As a substitute it is most available in goods where color or extreme lightness are not essentials. Being chemically inert, that is, free from any oxidizing tendency, it can be compounded with rubber in all proportions without injury to the new stock.

The sulphurized oil substitutes constitute a class by themselves and are distinguished as brown or white, although chemically they are essentially very similar. Any of the readily oxidizable, vegetable or drying oils combine freely, under proper conditions, with sulphur to form a more or less rubberlike mass. According to the selection of the oil and the mode of treatment, we get brown or white substitute. Such oils as linseed, rape, mustard and peanut are well adapted to make brown substitute. The process is a simple one, consisting in boiling any one of these oils or mixture of them in any proportion with flowers of sulphur. The operation may be carried on over a fire or by steam in a jacketed kettle. The proportions are generally about eighty per cent. of oil and twenty per cent. of sulphur. The reaction is complete in three or four hours at the heat of steam at a pressure of eighty pounds (325° F.)

It is well to boil the oil out of doors or in a strong draught of air to carry off the noxious vapors. The mixture should be thoroughly stirred while cooking.

Mustard oil reacts quite promptly with sulphur, but gives a firmer product and one that breaks rather shorter than that from the other oils named. It is best used in mixture with them. Linseed gives off the most disagreeable odor and has no special advantage in point of quality of product.

The white variety of oil substitute is made by treating refined mustard, rape, castor or cocoanut oils separately or in mixture with sulphur chloride either in the cold or with moderate heat.

The light, porous variety may be made by mixing with the oil a small proportion of sodium bicarbonate, which, under the influence of the sulphur chloride, generates gas in sufficient quantity to render the whole mass very spongy.

The operation should take place in an earthen or lead lined vessel and the sulphur chloride added slowly and stirred briskly into the oil.

The proportion of sulphur chloride to oil should be about one to eight, and of soda to oil about one to twelve.

When the chemical action is over, the product is allowed to dry for a couple of days before use.

A solid amber colored substitute is made in the same way and proportions, omitting the sodium bicarbonate.

All operations involving the use of sulphur chloride should be conducted in a strong draught and best in the open air, to avoid the evil effects of the vapors.

Chemically the use of these sulphurized drying oils in rubber compounds is bad. They exert a marked influence in shortening the life of the goods, because, by their active chemical nature, they hasten the oxidation of the rubber present to the brittle resinous products which give evidence of their existence in the compound by its loss of elasticity and by the hardening and cracking of the surface. There is little to be said for these oil substitutes from a chemical point of view. Their great practical value is entirely a matter of price, for they enable the manufacturer to cheapen the stock while maintaining the proper relative weight or specific gravity of the compound with reference to pure rubber.

The matter of specific gravity, or the ratio of the weight of any substance to that of an equal volume of some other substance taken as a standard, is a point of much importance. It governs the relation of pound price and piece price in rubber manufacture.

Specific gravity and the percentage of ash in a rubber compound once gave an indication of the amount of rubber present, but, since the extensive use of oil substitutes, they have no value as specifications of quality.

The specific gravity of caoutchouc or pure unvulcanized rubber is 0·915. It will therefore float in water about like ice, that is, nearly submerged. The oil substitutes are slightly heavier; enough so to sink in water.—India Rubber World.

ACETYLENE ON BOARD SHIPS.

ACCORDING to the Gas World, "Acetylene Gas and Its Probable Future Afloat" was the title of a lecture that Prof. Vivian B. Lewes delivered before the Institution of Naval Architects, on Thursday, April 8. Having briefly described the discovery and properties of commercial calcic carbide and acetylene, Prof. Lewes proceeded to discuss methods by which the latter might be applied on board ship. He said that the possibility of liquefying acetylene at pressures about those at which liquid carbon dioxide was produced so largely enabled considerable volumes of the gas to be compressed in the liquid state in small wrought iron or steel cylinders, and that it was in this liquefied condition that the gas would have to be utilized on board ship. At the freezing point, liquid acetylene would give about 370 times its own volume of gas. The pressure which liquid acetylene exerted upon the cylinders containing it varied with the temperature, but for all ordinary degrees of heat—say, from 60° to 75° F. —the pressure would be from 600 to 700 lb. on the square inch, while when heated to 86° F. the pressure rose to 1,000 lb. The cylinders, however, were generally tested to two or three times this pressure, so that there was an ample margin of safety.

During the past two years there had been two or three explosions caused by cylinders of liquefied acetylene, and these had given rise to a feeling that acetylene in this form was not safe; but it must be remembered that the introduction of a compound of this description, with comparatively unknown properties, must for a considerable period be hampered by accidents caused by improper usage; and there was proof that in each of the accidents that had occurred the screw plugs closing the cylinders were being tightened up with undue violence.

The Factor of Danger.—The factor of danger in liquid acetylene, and also in the compressed gas, was that acetylene was an endothermic compound, i. e., a compound in the formation of which heat is absorbed, instead of, as is usually the case, being liberated; and with such compounds this heat was again set free when they underwent decomposition, and added considerably to the violence of the action. At any pressure up to two atmospheres acetylene was perfectly safe from any explosive action per se, as at these low pressures high temperature, or even the detonation of a charge of mercuric fulminate in the gas, only caused local decomposition, and the explosion did not travel for more than a few inches from the spot where it was started; but directly the gas was put under more than two atmospheres pressure a red heat would initiate explosion through the whole volume, this being due to the sudden resolution of the acetylene into its constituent elements, carbon and hydrogen, with the liberation of the endothermic heat stored up in it. This all sounded very alarming, but when the conditions of danger were realized it was at once evident that, with rational treatment, cylinders of liquid acetylene were for all practical purposes perfectly safe, as, when kept in water tanks, nothing short of the surroundings being on fire would give the requisite temperature to cause danger, and on board a vessel the cylinders could easily be dropped overboard on a line until such danger had passed.

For Buoys and Lighthouses.—When it was considered that a cylinder holding 1 cubic foot of the liquefied gas would supply a burner giving a light of 32 candles for 400 hours, it was evident that there were great possibilities for it in the future on ships and yachts not fitted with the electric light. With a proper and special arrangement, highly efficient gas engines could be driven by it, and in small atmospheric burners it gave a flame of very high temperature; so that it was by no means impossible that the twentieth century might see a high speed torpedo boat driven by an acetylene engine, with an acetylene search light and an acetylene cooking stove, while some might even add to the equipment an acetylene torpedo, as a most effective "Sprengel" explosive might be made from liquid acetylene and chlorate of potash. These were dreams of the future, but there were certain spheres of utility ready for acetylene in which no plea of danger could be urged against its adoption. The first of these were floating buoys. At the present time there were four methods by which these could be lighted: 1. Electricity, 2. Compressed oil gas, 3. Com-

pressed coal gas enriched by gasoline. 4. Wigham's oil lamps. With electricity, the chance of the conducting wires being fouled by an anchor or dredge always existed; the compressed oil gas needed a small gas works and compressing plant; compressed coal gas and gasoline enrichment demanded the latter if not the former; while Mr. Wigham's oil lamps stood out as being both good and economical. There was room, however, for acetylene for this purpose, and a cylinder of liquid acetylene having a capacity of 1·75 cubic feet, fitted with a reducing valve, and stored in the bottom of the buoy, would give a clear white light of 32 candles for one month, and in cost would even now be about equal to compressed oil gas giving the same amount of light. If legal restrictions should prevent liquid acetylene becoming a commercial commodity, then compressed acetylene gas in cylinders, of the Pintsch or Pope pattern, could be effectively used, the gas giving a candle power three times as high as the best freshly pumped oil gas. For such purposes as buoy lighting and for use in lightships, the cylinders of liquefied acetylene seemed to be especially adapted, while the still more important function of an auxiliary light for use in lighthouses would be best carried out with the uncompressed gas. For lighthouse use the apparatus would be so rapid in action that, even with the holder empty, gas could be made and the lantern burning within a very few minutes of the breakdown of the electric apparatus.

Penetrative Power.—Prof. Lewes next spoke of the penetrative power of different lights, remarking that the usefulness of a light for signaling purposes depended upon its power of passing through the atmosphere without change or absorption. Measuring the penetrative powers of different lights by means of a cell containing an artificial haze, he obtained the following data, the figures being the percentage of light lost in passing the cell:

Coal gas	11·1
Oil gas	11·5
Acetylene	14·7
Incandescent gas (Welsbach)	20·8
Electric arc	26·2

Of course, these figures merely give the loss of light in passing through the thickness (3 in.) of fog solution employed; but it was evident that they would also give approximately the ratio of the penetrative power of these illuminants in mist-laden air.

Automatic Lights.—A minor, but, at the same time, very important, use to which calcic carbide could be put was in the manufacture of signal lights of the same character as the Holmes lights now in use. He had come across several specimens of carbide of Continental manufacture which gave acetylene spontaneously inflammable in air. On investigating this phenomenon he found that it was due to the carbide containing a certain proportion of calcic phosphide, which, on contact with water, gave enough spontaneously inflammable phosphureted hydrogen to ignite the acetylene. It naturally occurred to him that this might be utilized in making very valuable signal lights, of the same character as Holmes lights, for indicating the position of life belts, torpedoes, etc., as if the Holmes cartridge were filled with a mixture of calcic carbide and phosphide, only a small proportion of the phosphide served to make the acetylene, rapidly evolved on contact with water, ignite on coming in contact with air, and the light-giving power of the flame was far more effective than that emitted by the phosphide alone. Moreover, the cartridge could be made in the form of a hollow tube, so weighted as to float with its open end downward; and if a small cage of the mixed carbide and phosphide were fixed in the upper portion, and a tube with a small burner let into the top of the cartridge, the gas escaping spontaneously lighted, and burned with a flat flame of such intensity that it could be seen for a very great distance. He should imagine that if such a candle were attached to the life buoys, flung overboard at night, it would not only guide a swimmer to the buoy, but also mark the direction in which the ship's boats had afterward to proceed.

THE MECHANICAL SHIPMENT OF COAL.

The continual increase in the production of coal mines, along with the extension given to carriage by water, has led to an improvement of the methods usually employed for the shipment of the coal. Mechanical processes are the only ones that permit of rendering this operation both rapid and economical. For this reason, numerous solutions of the question have been proposed, and the systems employed at the mines almost always vary from one exploitation to another.

The most frequent process consists in the use of cars whose boxes are jointed upon their frame and are capable of tilting to one side. This is a very simple solution, but it requires a motive power and an installation of special lifting apparatus.

At the mines of Lens cranes are installed upon the locomotives, while in other exploitations the tilting motion is effected through a compressed air apparatus somewhat similar to the brake apparatus in use upon railway lines and which the engineman can maneuver from the locomotive.

The idea has occurred to do away with the use of these lifting apparatus by adopting cars similar to those used for carrying filling material upon the Panama Canal. The box of these cars was likewise jointed to the frame, but its center of gravity projected with respect to its suspension point. A bolt held the box in its ordinary position, and as soon as it was drawn, the tilting motion took place under the action of gravity.

The saving that this arrangement seems to afford is illusory, since, although it does away with the use of lifting apparatus, it thereby necessitates an increase in the dead weight of the cars in order to have a frame that shall remain in perfect equilibrium upon the rails at the moment that the box of the car is tilted. Consequently, the cost of hauling the cars from the mine to the shore is largely increased.

Besides, this system presents another inconvenience, and that is that the tilting motion is not uniform, but, on the contrary, gives rise to an inevitable acceleration, with the result that the load is dumped quite abruptly, the coal is broken in small pieces, and the proportion of waste is increased.

An endeavor has also been made to effect the shipment by means of a sort of seesaw, that is, of a board pivoting upon an axis and giving the cars a sufficient inclination to allow the coal to slide into a loading hopper. These apparatus, which were hydraulic, and consequently necessitated a special motive power, were in favor for a long time. We believe it of interest, from this view point, to make known the arrangement devised by M. Malissard-Taza, superintendent of Madam Taza-Villain's works at Anzin, since it permits of dispensing with the use of an external motive power, the apparatus operating simply under the action of the weight of the car to be discharged. This very ingenious arrangement consists of a metallic platform, F, oscillating around two journals, and upon which the car to be dumped is so placed that its center of gravity shall be eccentric with respect to the journals. A piston, P, working in a cylinder, C, completely filled with water, is connected with the platform by its rod and a jointed connecting rod, B, whose extremity is fixed on the opposite side at the center of gravity of the car with respect to the axis of the journals.

The upper and lower parts of the cylinder communicate through a conduit of small diameter provided with a cock, R. Beneath the platform, a pendulum composed of two counterpoises is so suspended that its center of gravity shall be in the same vertical plane as the axes of the journals.

After the car has been placed upon the platform it is held firmly at its two extremities and then tends to cause the platform to tilt; but, since the cock, R, is closed, the piston, in consequence of the incompressibility of the water contained in the cylinder, prevents such motion. As soon as the engineman opens the cock by means of the system of levers, L, he allows the water contained in the upper part of the cylinder to escape. This flow may, moreover, be easily regulated by a maneuver of the cock so as to render the tilting motion as slow as may be desired. The action of the counterpoises, which was null at first, keeps on increasing in measure as the inclination becomes greater. This pendulum therefore serves as a moderator.

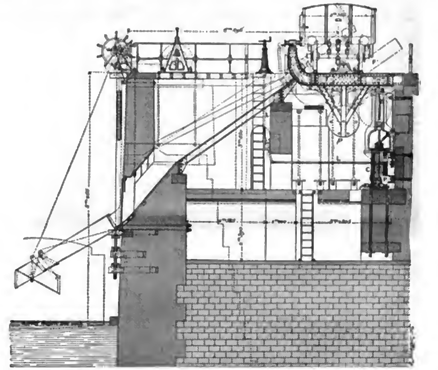

Fig. 1.—DIAGRAM OF THE MALISSARD-TAZA INSTALLATION FOR THE SHIPMENT OF COAL.

The doors of the car are movable around a horizontal axis situated at the highest part of the box, and, as soon as the latter begins to incline, they tend to open through their own weight and the thrust of the load; but they are kept closed by a bolt that is not withdrawn until the platform has reached the maximum inclination of 38°. At this moment the coal slides gently into the hopper. The return of the empty car to its horizontal position is determined by the action of the pendulum, and this motion is regulated likewise by the hydraulic brake.

The hopper into which the coal falls is in two parts, one of them fixed and the other movable. The former has quite a feeble inclination that renders the sliding of the coal easy and free from shock, and the other part can be easily maneuvered, and permits of distributing the coal in all portions of the boat.

Fig. 2.—MECHANICAL SHIPMENT OF COAL.

This installation is completed by an apparatus for towing by manual power. This consists of a windlass around which winds an endless steel cable. Upon connecting this cable with the boat, it is possible to move the latter in two directions by maneuvering the windlass.

This apparatus, which is constructed for 10 ton cars,

permits of the shipment of from 20 to 25 car loads an hour, that is to say, of from 2,000 to 2,500 tons of coal per day of ten hours. It requires but two men for the operation.—La Nature.

ENDOSCOPY.

DURING the few months following the discovery of the X rays it was necessary to use a photographic plate in order to obtain the image of an object invisible to the naked eye. Since then, Edison, Salvioni

FIG. 1.—DUCRETET & LEJEUNE'S ARRANGEMENT FOR THE TREATMENT OF TUBERCULOSIS BY X RAYS.

and many others have substituted for the sensitized plate a fluorescent screen that permits the human eye to see the interior of the body as easily as if the corporeal envelope were as transparent as glass.

In Italy, along about 1600, a peasant having calcined a stone, perceived that it emitted a light in darkness after it had been exposed to sunlight for some time.

This was, as now known, sulphate of baryta, which had been converted into sulphide of barium by calcination. Chemistry afterward found other bodies that are possessed of these curious properties, such as sulphide of zinc, platinocyanide of potassium, tungstate of calcium, etc. All these bodies possess, to a different degree, the singular property of emitting luminous radiations in darkness without their temperature differing from that of the surrounding medium. The ultra-violet radiations of light produce a marked action upon phosphorescence. The X rays possess the same property to a high degree.

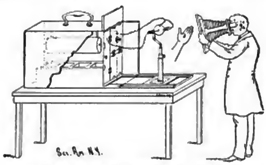

FIG. 2.—M. SEGUY'S APPARATUS IN OPERATION

Now, it will be recalled that it was owing to some paper covered with platinocyanide of barium that happened to lie near a Crookes tube that Dr. Roentgen discovered the X rays.

There have therefore been constructed screens formed of a wooden frame upon which is stretched strong paper covered with a chemical substance capable of becoming fluorescent under the action of the X rays. Upon interposing between this screen and the tube that produces the rays an object opaque to the eye, it becomes immediately visible upon the prepared surface. Thus, for example, if one puts his hand between the two objects, it at once disappears and nothing but the bony skeleton is perceived.

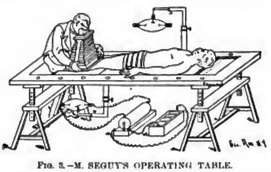

FIG. 3.—M. SEGUY'S OPERATING TABLE.

The consequences and advantages of this valuable observation will be at once seen. A patient may be "visited," without any trouble or suffering on his part.

It is now possible, by employing electric currents of varying strength, according to circumstances, to witness the beating of the heart, the inflation of the lungs, and the motions of the diaphragm, and to perceive the liver, the spleen and the different glands. As for the bony framework, that has no longer any secrets. The apophyses and the articulations stand out with wonderful distinctness and the slightest osseous traumatisms are revealed much better than with percussion and auscultation.

Certain affections of the bladder and aorta are discovered by means of this new method of investigation. Finally, the lesions of the lungs in consumptives are likewise observable, and this terrible disease will, perhaps, be cured by the action of the X rays. Numerous observations have already been made by Profs. Lortet and Genoux, of Lyons, and by Drs. Vilain, Rendu, and Du Castel, of Paris. It really seems as if an evident action took place in tuberculous subjects and those afflicted with infectious diseases. Moreover, it is unquestionable that prolonged radiations produce upon the skin a rubefaction analogous to that which would be produced by a strong insolation or a sinapism.

Since the entire thickness of the body is traversed, such action must not be external merely, and the subcutaneous walls have a marked sensitiveness. The action of the X rays appears to destroy the toxines secreted by microbes, and which are the cause of the disease above indicated. It is so certain that therapeutics will make use of this method that special apparatus are already constructing, such as those represented in Figs. 1, 2 and 3. The first figure shows the arrangements made by Messrs. Ducretet and Lejeune, for the treatment of affections of the chest. The other apparatus, which were devised by Engineer Seguy, are designed to facilitate all radiographic operations (taking of photographs) or radioscopic ones (vision with a fluorescent screen). Fig. 3 shows a patient lying upon a special operating table. The center of this table is hollowed out, and, through grooves, permits of sliding in negative frames containing sensitized photographic plates designed to remain as a witness in discussed and difficult cases. In more general cases, the diseased member is examined with a sort of opera glass, which contains the fluorescent screen. This glass permits of observing in broad daylight. It forms part of a very simple apparatus inclosed in a box containing the accumulators, the Crookes' tube and the transformer (Fig. 2).

It happens, and more frequently than might be thought (as clinics can prove), that certain bodies enter the organism in an accidental way—coins into the œsophagus, pins and needles into the hand or foot, projectiles from firearms into the body, etc.

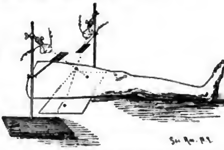

FIG. 4.—BRUNEL'S ARRANGEMENT FOR LOCATING FOREIGN BODIES IN THE HUMAN ORGANISM.

Formerly, the exploration in order to locate such bodies was a lengthy and painful operation. Thanks to the X rays, and to the following arrangement devised by the writer of this article, the place of the object is at once indicated without any suffering on the part of the patient. Say, for example, that a revolver ball has entered the thigh. The wounded member is arranged as shown in Fig. 4. Two Crookes tubes are placed above small glass or metal diaphragms and a photographic plate is placed beneath the member. Upon the plate we shall therefore have a projection of the ball at two different places. The shadows will be projected at AB and A B (Fig. 5). We shall have the images at

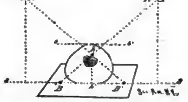

FIG. 5.—GRAPHIC DETERMINATION OF THE POSITION OF A FOREIGN BODY.

BB'. It will only remain to measure the distance of the tubes, AA', and to transfer such measurement (all proportions being kept) to a sheet of paper, as shown in the diagram. The height, h h, of the triangle BhB', measured from h to h, will give the exact situation of the foreign body, e, in the part, O, or its distance to the tangent line, s s'.

It may happen, also, that it is desired to radiograph a definite portion of an organ and that it is difficult to know the exact time that it will require to take the part desired. By means of my "doseur" all tentative efforts are avoided. This apparatus is very simple. It consists of a metal plate provided with five apertures, A B C D E, four of which may be closed by means of a shutter of the same metal.

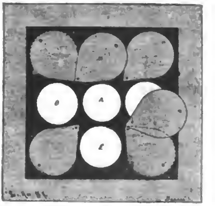

FIG. 6.—THE BRUNEL DOSEUR.

The plate may be surrounded with a wooden frame. When it is desired to obtain an image of a certain organ, a radiographic operation is first performed. The doseur is arranged beneath the Crookes tube in opening all the apertures, and an exposure is made for a fraction of a determinate time. One shutter is then closed and another exposure is made for the same length of time,

and one continues thus until the four apertures are closed. When the operation is finished, the part, A, will therefore have made an exposure five times longer than the first aperture, and the others in proportion. The plate having been developed, we shall have five very distinct circumferences upon the negatives. We shall then see, according to the part most conspicuous, the exact time that must be taken to obtain an image of the organ designated. This preliminary operation will not prove a loss of time, since otherwise we should be obliged to take three or four negatives before obtaining a good result. All those who have experimented with X rays up to the present know this well.

Among all the operations that have been performed by means of the X rays, I shall mention but one, and that an extremely interesting one. A patient who was diabetic to the last degree, and who dreaded the smallest surgical operation that might bring on a flow of blood, had a piece of a needle in his foot that prevented him from walking, and of which it was necessary to rid him through the extirpation of the metal.

Dr. Niquet and M. Radiguet tried the following operation. They located the exact position of the needle by means of radioscopy, and then endeavored to attract it by means of a powerful electromagnet. In two operations of one hour they succeeded in extracting the piece of metal without drawing a drop of blood.

At present, astonishing operations that no one would have dared to attempt a few months ago are daily performed in clinics by means of the X rays.

But although X rays are used, the nature of them is not as yet known. Are they cathodic rays formed in the interior of the tubes and a portion of which alone passes through the glass? Is it the glass rendered fluorescent under the action of these rays that emits the X rays? Finally, is it a peculiar electric phenomenon?

These are the questions that confront those scientists who are occupying themselves with this obscure subject.

However, every day introduces a new element into the observations. Thus, M. Radiguet has observed in his laboratory an order of phenomena that are mysterious and confusing to the uninitiated when they pass

Fig. 7.—PHENOMENA OF LUMINESCENT CRYSTALS DISCOVERED BY M. RADIGUET.

into the darkness. The tube that produces the radiations being well wrapped in black cloth, and the darkness being absolute in the laboratory, all the crystals, glasses, gas globes and electric light bulbs are seen to become gradually illuminated. This seems like magic. If we take a glass provided with facets, the effect is wonderful. If the glass be moved about, the arm and hand being invisible, it will seem as if the glass is moving of itself without being held, and the same is the case with all glassware. It is weird and mysterious. Porcelain, enamels and brilliants also have the property of becoming illuminated under the action of the X rays. The luminous phenomenon becomes less marked at a distance, and this is perhaps the reason why it had never been observed up to the present.

What is the cause of this luminosity? It may be said that under the action of the X rays the molecules of the glass change state and emit ultra violet rays. Now, aside from sulphate of soda, glass contains at least a certain quantity of silicate of baryta. May it not be this substance, incorporated with the glass and converted by heat into sulphide of barium, that emits the fluorescence? However this may be, M. Radiguet's observation is interesting in more than one respect. It offers a new road to researches and to practical applications that were immediately seen by its author; for example, the re-enforcement of photographic action upon sensitized plates and the construction of opera glasses and eye glasses that emit no light and that constitute X ray glasses, which are very useful to operators.

Although, then, the mystery that hovers over the identity of the X rays still exists, the numerous and beneficial applications that are made of them are capable of consoling scientists and investigators for not having made a step in the way of solving this new problem in physics laid before them by the celebrated professor of Wurzburg.—G. Brunel, in La Revue des Revues.

On May 30, the Swiss sections Tug-Golden and Luzern Immensee on the Berlin-Milan line were opened. The result is a shortening of the journey by one hour and the leading of the line through more picturesque surroundings.—Uhland's Wochenschrift.

THE COLOR OF BLOOD.*

By Felix Oswald, B.A. Lond.

"Blood red" is so familiar an adjective of color as to readily convey the impression that the blood of all animals is red. Such, however, is far from being the case, for although the possession of red blood is a characteristic common to all vertebrates,† yet when we come to examine the invertebrates, which are far more numerous both in species and individuals, we find that blood of a red color is a relatively rare occurrence. In the majority of cases it is colorless; but it may be even green, blue or yellow.

It has often been a subject for speculation why the life fluid of higher animals should have so vivid a hue, seeing that it is normally concealed from view, and seldom or never plays any part in determining the surface coloration, excepting in a blush. It is only a partial explanation to say that the redness is due to hæmoglobin, and that it is an inherent physical characteristic of this body. The reason for the red color is quite as difficult to explain as to account for the distinguishing colors of gold, silver or copper. It is no exaggeration to say that hæmoglobin is the most important substance in the complex combination called blood, for it is hæmoglobin which absorbs oxygen from air or aerated water, conveying it to all tissues in need of that vital gas, receiving carbon dioxide in return, and finally giving up the excess of this waste product of combustion to the surrounding medium. Hæmoglobin can be artificially separated from blood to form crystals, differing in shape according to the animal.

Usually, as in man, they take the form of prismatic needles or rhombic plates. It can furthermore be resolved into hæmatin, a dark brown amorphous powder, and an albuminous substance called globulin. Under the spectroscope it exhibits a very characteristic absorption spectrum,‡ by means of which Lankester and others have been able with absolute certainty to demonstrate its presence in the blood of certain invertebrates.

The hæmoglobin in the blood of vertebrates is contained exclusively in little circular disks,§ the red corpuscles. In the few instances in which it occurs in invertebrate animals, it is generally diffused in the plasma, e. g. in the blood of the earthworm and many other Chætopod worms, in some leeches (the Gnathobdellidæ), in some Nemertine worms (e. g. Polia), in the fresh water mollusk Planorbis, in a few small crustaceans (Cheirocephalus and the water flea Daphnia) and in the so-called bloodworm (the larva of the midge, Chironomus). Less frequently it is found concentrated in corpuscles, e. g. in the bivalve mollusks, Solen legumen and Arca noæ, in a few Chætopod worms (e. g. the Polychæta Glycera and Capitella), in some Gephyrean worms (Phoronis, Thalassema, Hemingia), in some Nemertine worms (e. g. Cerebratulus) and in a few Echinoderms (Thyonella, a sea cucumber, and Ophiactis, a brittle starfish).

These examples occur sporadically among such widely separated groups of animals that hæmoglobin must evidently have been independently acquired several times in the animal kingdom. It is clear that the possession of it does not in itself indicate any relationship.

Arterial blood is scarlet owing to the hæmoglobin containing a rich supply of oxygen; on the other hand, the dark purple color of venous blood is due to an excess of carbon dioxide. Both gases, however, are present in arterial as well as in venous blood; indeed, the former actually contains more carbon dioxide than oxygen. The difference in color, therefore, is merely a question of varying proportion, for an artificial solution of hæmoglobin changes color from purple to scarlet when a current of oxygen is passed into it. It is indeed probable that the oxygen enters into a state of unstable chemical combination with the hæmoglobin, and that the red corpuscle does not merely hold it as a sponge.

In this way the presence of hæmoglobin is an absolute necessity for the more remote internal parts of the body to receive a due supply of the vivifying oxygen and to get rid of the waste carbon dioxide. Indeed, it is doubtful whether vertebrates could have reached their great size and dominant position in the world without the possession of hæmoglobin in its valuable capacity for storing up oxygen. Hæmoglobin, however, is not confined to blood, but is contained in the voluntary muscles of the higher vertebrates (hence the red color of raw flesh) as well as in the tissue of the heart. Among fishes, however, it is entirely absent from the muscular tissue of the body, excepting in the fin muscles of the graceful little sea horse (Hippocampus). Among invertebrates it is found in the muscles of the pharynx of a few mollusks (Chiton, Patella, Littorina, Paludina, Lymnæus and Aplysia), but strange to say, not in the blood of these creatures. In the Chætopod worm, the sea mouse (Aphrodite), it is even restricted to the nerve centers.

In reviewing the habits of those invertebrates which possess this valuable colored substance, we are able to infer that either (1) they show increased activity compared to their nearest relations, as in the case of the Neapolitan razor shell (Solen legumen); or (2) they live under circumstances in which oxygen is not easily obtained, as in the case of the bloodworm in the mud of stagnant pools, etc.; this is probably the main cause, and the power of being able to store up oxygen, whether in blood, muscle or nerve, must be a valuable aid in such adverse conditions; or (3) there may be a combination of these reasons, as in the leeches, which inhabit miasmic localities and yet show great activity, leaping upon any unfortunate man or animal invading their marshes. In the case of the bloodworm, Professor Miall has shown that it could live as long as five days in water that had been deprived of its oxygen by boiling.

The view that hæmoglobin has been primarily acquired merely as an expedient in conditions unfavorable to easy respiration is supported by the fact that the insect Chironomus possesses it only in its larval (bloodworm) stage, but when it reaches its final and winged state its blood is colorless. The disappearance of hæmoglobin in the blood of the perfect insect is indeed a highly remarkable fact; yet it is not surprising when we consider how thoroughly air is distributed to every tissue in an insect's body through the air tubes or tracheæ. The excessively delicate ramifications of these tracheæ extend into every muscle and even penetrate between the cells of the eye and of the nerve centers; hence, since every part of the body has direct access to the oxygen of the air, there is no need for this gas to be conveyed by the blood; consequently the circulatory system in insects is very imperfectly developed, and the blood is colorless.

Hæmoglobin does not, however, stand alone in the animal kingdom in its function of storing up oxygen. In the blood of certain tube-forming worms (Sabellidæ and Serpulinæ) a greenish substance, chlorocruorin occurs which has similar powers of absorbing oxygen and yielding it up to all parts of the body in need of it. It is, therefore, within the range of possibility that if the ancestor of the vertebrates had developed chlorocruorin in its blood in preference to hæmoglobin, our blood might be green, instead of red, and our admiration aroused by a verdant instead of a pink complexion.

* From Science Gossip.

† There appear to be only two exceptions to this rule, viz., the lancelet (Amphioxus), which is the lowest vertebrate, and the transparent little fish Leptocephalus, now regarded as the larval stage of the eel.

‡ It is interesting to note, as Prof. Church points out, that hæmoglobin possesses the same conspicuous absorption band in the ultra violet as chlorophyl, although, of course, the rest of the spectrum is very different.

§ Elliptical in fishes, amphibians, reptiles, birds and in the camel family. In the lampreys, however, the red corpuscles are circular.

MACHINE TO LOCATE FIRES.

Although the city of Vienna has an up-to-date fire alarm system, there is, however, constantly maintained a fire watch of several men on duty at all times in the tower of St. Stephen's Cathedral, the highest point in the city. For the purpose of locating a fire, there is in use a novel instrument known as the "topescope," which is said to do its work in day or night with unerring accuracy, says the Boston Journal of Commerce. The topescope consists of a good telescope, which is solidly attached to an arrangement of levers, while graduated sections of a circle are arranged horizontally and vertically in such a way that the moving of the telescope sideways or up and down results in a change of position of the hands attached to the levers in reference to the graduated scales. It is obvious, the stability of the apparatus being assured by their being firmly fastened, that whenever the telescope is focused upon the same object the hands will point to the same figures on the horizontal and on the vertical sextant, and, since an index of the whole city has been made, it is a matter of but a few seconds when a fire is discovered at night to direct upon the spot the topescope on the respective side, to read off the numbers, to look up the object and to wire it to the central fire station, with all the details observed. Local conditions are, of course, necessary for the successful operation of this apparatus, but in this case they are almost perfect. St. Stephen's tower is over five hundred feet high; the great area of the city is situated in the broad valley of the Danube, allowing an uninterrupted panorama to the city limits. The atmospheric conditions are also favorable. The topescope up there works so accurately that even at night the exact house and number were often given to the central by the watchman on the tower, while the next fire alarm box, being at a distance of three or four blocks, could not have given the exact location of the fire, and this would have delayed the arrival of the fire department accordingly.

The Sanitary Trustees of Chicago will build the largest swing bridge in the world across the drainage canal at Thirty-first Street and Campbell Avenue. Its total length will be 400 feet 5 inches, and its width will be 120 feet. The height of the center columns will be 98 feet; headway under the trusses for trains, 21 feet; headway under the bridge, 18 feet; and depth of water in the channel, 24 feet. The bridge will be of steel, weighing 7,000,000 pounds. It will be capable of supporting a train load of 8,000,000 pounds. The total cost is estimated at $700,000, including the machinery. Three railways will use the structure, crossing on eight tracks. The turn table will have a diameter of 80 feet, and the bridge will be swung in one minute, probably by electric power.

ENGINEERING NOTES.

The first home-manufactured locomotive in Japan was built in 1892-1893.—Prometheus.

The municipal council of Berlin has just decided, by a large majority, that henceforth the trolley system is to supplant the horse cars hitherto run on the Berlin tramways. The proposal of introducing cable cars has been rejected for the danger which such traction presents, both in technical matters and in hygiene.—L'Energie Electrique.

The spontaneous ignition of coal was known in antiquity. Theophrastus (320 B. C.) in De Lapidibus says: "At Bina (Thrace) there are found brittle stones which will burn, and have long been used as fuel, but they give an offensive smell. In some mines they find spinus, which will ignite spontaneously if crushed, heaped up and moistened." A writer of the eighteenth century attributes the spontaneous ignition of coal to the sulphur contained therein.—Prometheus.

Two tunnels are to be built under the Danube at Budapest. They are to connect the Parliament building with the Romben Platz, and the Boraros Platz with the Kelenföld respectively. The two tunnels are to be built 15½ meters (about 50 feet) below the normal level of the river and are to be 10 meters (32¾ feet) high. There will be a partition dividing each tunnel into an upper and a lower part. The upper part will be for pedestrians and tram cars, the lower part for ordinary traffic.—Uhland's Wochenschrift.

The system of Smith and Granville for connecting lighthouses with the coast is one of the most practicable. At the coast station two metal plates with cables attached are sunk into the earth. At the lighthouse two similar cables are connected to earth in the same way, but here some delicate instrument, such as a reflecting galvanometer, is included in the circuit. An alternating current is sent at intervals through the cables on the land station, and the secondary current produced in the lighthouse cables deflects the needle, so that messages can be sent according to a prearranged code.—Glaser's Annalen.

An ingenious way of simultaneously making and laying drain pipes is used by R. Dockery, at Los Angeles, Cal. The whole thing is done by a rather primitive machine. This consists of a tube, whose diameter corresponds to the outer diameter of the pipe to be produced, in which is fixed from inside a cylindrical plug, leaving a space for the clay to pass. The clay is supplied by a funnel and pressed out by the plug itself, which toward its internal extremity is threaded. During the operation the machine is sunk into the channel dug for the pipes and moves along in plow fashion.—Monatschrift für Oeffentlichen Baudienst.

The production of iron and steel wire nails in the United States in 1896 amounted to 4,719,860 kegs of 100 pounds each, compared with 5,841,403 kegs in 1895, a decrease of 1,121,543 kegs, or over 19 per cent. In 1894 the production amounted to 5,681,801 kegs and in 1893 to 5,095,945 kegs. The wire nails produced in 1896 were manufactured by seventy-three works, thirty-one more than were in operation in 1895. The production of 1896 represented 210,708 gross tons. The total production of cut nails in 1896 was 1,615,870 kegs of 100 pounds each, against 2,129,894 kegs in 1895, a decrease of 514,024 kegs, or over 24 per cent. There has been a steady decline in the production of cut nails since 1886, in which year the maximum production of 8,160,973 kegs was reached. In 1896 the production of wire nails exceeded the production of cut nails by over 3,103,000 kegs. The production of cut nails in 1896 represented 72,137 gross tons. Eleven States made cut nails in 1896.

A thirty five foot entrance to New York harbor is strongly advocated by the Chamber of Commerce and the transatlantic and even coastwise steamship lines, says Engineering News. The river and harbor act of June 3, 1896, directed the Secretary of War to ascertain the location and cost of obtaining a depth of 35 ft. at low water mark from the "Narrows to the sea," and a report upon this head was submitted in January of 1897 by Colonel G. L. Gillespie, Corps of Engineers, U. S. A., and an abstract of this report was given at that time in this journal. A resurvey has now been ordered and the work is being carried on under Lieutenant-Colonel William Ludlow, Corps of Engineers, U. S. A., the successor of Colonel Gillespie. Lieutenant-Colonel Ludlow says that it is not proposed, as reported in the press, to deepen the Coney Island Channel to 35 ft., though that channel may be deepened to 16 ft. to better accommodate coastwise and excursion steamers. The actual work to be performed cannot be reported upon until the present surveys are completed, and all locations, plans and estimates of cost given in the press accounts are premature and unfounded.

The relative cost of transportation by railway and canal is thus expressed by Mr. Leslie R. Robinson in a paper on "Mechanical Propulsion on Canals," lately presented to the London Institution of Mechanical Engineers:

Items of Cost.	Railway.	Canal.
Maintenance of way	13	0
Maintenance of works	7	2·3
Repairs of rolling stock	19	6·0
Traction	16	8·0
Traffic expenses	30	6·0
General charges	15	15·0
Interest on capital	100	33·3
Totals	200	70·6

He says that the three principal causes why transport of heavy goods by canal costs only about one-third as much as by rail are the following: On a canal there is no cost corresponding to the wear and tear of rails, ties or track appliances, though the cost of maintaining banks and locks must be taken into account. In canals there is a corresponding saving of the repairs on engines and rolling stock resulting from running on a rigid permanent way. The most important cause for economy on canals, however, is the absence of vibration and the smaller magnitude of the works themselves. The table given is taken from the evidence of Mr. Conder before the parliamentary select committee on canals.

ELECTRICAL NOTES.

An enterprising burglar has at last ventured to use the means minutely described in some of our contemporaries for burning holes in a safe, says the Electrical World. A few days ago the bank of Messrs. Rogers & Son, at Chagrin Falls, Ohio, was found open and on the floor in front of the safe were found burglars' tools, a pile of sand, carbons and wires leading to the tracks and trolley wire of the street railway, near the building. It is said that big holes had been melted in the combination lock and the molten metal caught in the trough of sand on the floor below. The current had been shut off from the railway line during the night, and it is supposed that this compelled the burglars to desist.

Some Syracuse lads indulged in some "fun" with live electric wires recently. A wire which had been employed as a guy to support an electric light pole had come down and crossed a live wire in falling. The boys attached it to a piece of barbed wire from a neighbor's fence, and laid the latter across the cycle path, from which wheelmen would attempt to remove it in passing and receive a shock. Another trick was to throw it over a trolley wire, making a short circuit and stopping the cars. One boy, barefooted, playing about the spot, grasped the wire and ran his hand swiftly across a point where the insulation had worn off. He was standing with bare feet on the tracks of a disused trolley line at the time. The boy died in about eight minutes. He had received a shock from about 2,500 volts.

The Street Railway Review gives the following information as to the operating expenses of the Calumet Electric Railway, Chicago. The company operates 75 miles of track, all of it double except one mile. The number of cars in use varies from 37 in winter to 200 in summer. There are practically no grades on the line. The distance from the power house to the farthest terminal is 5½ miles. The coal used costs from $1.15 to $1.50 per ton. The road began operating in 1891, and has constantly extended its lines, having 10 miles in 1892, 23 miles in 1893, 53 miles in 1895, and 70 miles in 1896. John MacFayden, general superintendent of the Chester Traction Company, Chester, Pa., says that on that road the operating expenses for the year 1896 averaged $0·0759 per car mile. The company operates 28 miles of track, only two of which are double track; at the extreme end of one division, which is 8 miles from the power house, is a 6 per cent. grade, 1,500 feet long. There are several other grades of from 8 to 10 per cent. The average number of cars operated is 28 per day.

Electricity is finding uses in oil mining in Pennsylvania and promises to develop a large field of application in this direction. An oil company is erecting on one of its farms in Pennsylvania an electrical power plant to supply power for pumping all of its wells in that vicinity and also for drilling new wells. At present all this work is done by a small steam engine at each well, involving long steam lines, great waste of fuel and large expense for attendance. It is believed that a great saving will be effected by having a single power house with electrical transmission to a motor at each well. This plan has been adopted to a limited extent by other companies for pumping oil, but probably the only well hitherto drilled by electric power is the one put down by the Westinghouse Electric and Manufacturing Company near its factory at East Pittsburg, Pa. As the production of oil is a very large and important industry in this section of Pennsylvania, it is quite probable, according to the Electrician, that if the plan above referred to proves to be successful, it will pave the way for a very extensive use of electric power in the oil regions.

The Illustrated American has a description of a large electromagnet with pointed poles (both are pointed) designed for extracting iron filings or splinters that have lodged in the eye. Our contemporary gets quite graphic in describing the operation. "The instrument has a drawing force of 16 lb. As the eye of the patient is pressed toward its point the subtile magnetic power begins to draw upon the splinter. The metal, struggling for release, bulges the eye from the socket. If not too deeply embedded, the splinter will yield to the force, and, leaving the eye, become attached to the point of the magnet. But, as only too often occurs, the metal may strike with such force as to perforate the coating and drop down into the cavity of the eyeball. Especially is this the case when it passes through the iris or the pupil. One instance was mentioned by the attendants of the hospital of a splinter which passed entirely through the eye and lodged in the coating on the other side of the ball. Applied to the eye the big magnet will reveal with accuracy to the skilled sight of the physician the position of the troublesome particle. Knowing this, he can remove it by an operation. Only in the most desperate cases need loss of sight follow."

While an armature has been defined as a bundle of wires cutting magnetic lines, with suitable connections for carrying off the induced current, it is this "bundle of wires" which is the vital part of our electric systems to-day, and has given more trouble and study than all the rest of the system combined. The working capacity of armatures, according to Mr. G. Moffat, in the New York Electrical Engineer, may be said to be limited by two things, sparking at the brushes and the heating of the armature itself. Of these, the heating of the armature has been found the more troublesome of the two on account of the difficulty in overcoming it. To stop sparking at brushes, unless a structural defect, is much more easily accomplished. Besides the element of risk accompanying undue heating, there is a large waste of power, and power means money. In some machines tested, the author has found it necessary to reduce the load almost 50 per cent. before reasonable heating loss was met with. The maker's guarantee that the machine's capacity is 100 per cent. above what is found safe will not bring back the power thus wasted. The heating arising from the friction of brushes, if excessive, may be remedied by better brushes, springs no stronger than necessary to make perfect contact, a true commutator, and, if necessary, a little light-bodied oil applied occasionally which will quicken the polish. The main requisites for cool running would then seem to be: machines run at their true capacity, properly insulated, laminated cores and thorough ventilation.

MISCELLANEOUS NOTES.

According to the lately published statistics of 1895, the number of ships sailing into non-European ports (inclusive of the territories under German protection) has decreased by five; the tonnage, however, has risen by 84,439.—Uhland's Wochenschrift.

A novel system of allowing reduced fares has been instituted in Germany. According to new regulations, holders of ten third-class or eight second-class tickets, i. e., of a whole coupé, are entitled to a free return journey, ten days being the term allowed.—Uhland's Wochenschrift.

At the end of the year 1894 Japan had only twelve steamers of more than 3,000 tons and twenty-nine of more than 2,000. Now there are ten steamers of more than 5,000 tons, two of over 4,000, thirteen of 3,000 and over, fourteen of more than 2,000 and sixty over 1,000 tons. And building is constantly going on, so that there is a demand for increased harbor accommodation. Japan is threatening to become the greatest power on the Pacific.—Uhland's Wochenschrift.

Gas pipes have been made of paper in England. They are said to answer their purpose very well, particularly for underground conduits. They are made of any length required, and passed through liquid asphalt, to render them gas and water tight. It is said that these pipes resist the dampness of the ground, high pressure, and other inconveniences, better than the usual metal pipes. It is, however, doubtful whether good iron pipes coated inside and out with asphaltum are not superior to the cellulose article.—Prometheus.

A new material for paving streets is found in straw. A Polish engineer has designed a method and machinery by which straw is bound with wire, immersed in various hot liquids, and finally in pitch. The straw is then cut into cubes, much like those used for wooden pavement, and is ready for use. These blocks are said to be considerably cheaper than wood, and quite as durable. The straw used must be from unthrashed corn, otherwise it is broken and unfit for the process. The inventor has devised a machine which cuts off the ears from the straw.—Monatschrift für Oeffentlichen Baudienst.

Dr. Joseph Wittlin has made researches as to the value of the various modes of freeing roads from dust. He found that the action of the sun's rays was deadly to bacteria, but that the sprinkling of streets counteracted their effect. So the method of conveying the dust dry to the gutters by means of brushes and then carrying it to the drains by a stream of water is more commendable than the usual sprinkling. But better still is the course taken in England and some parts of America, where the dust is swept together and destroyed by combustion.—Monatschrift für Oeffentlichen Baudienst.

A simple process for bronzing steel, iron and copper is described in Revue de l'Electricité. The article to be bronzed is coated with vaseline, and then heated to redness, and left to itself till the desired color is attained. A second application of vaseline may be necessary if the first supply is burnt away before this point is reached. The article is then allowed to cool and cleaned of the carbonaceous matter clinging to it by rubbing with vaseline. The tint, which resembles that of gunmetal, is probably due to superficial oxidation. The bronze is very permanent, and particularly suitable for steel.

In connection with the recent state procession of the Queen to St. Paul's Cathedral some interesting particulars have been published by the Buildings Committee of the London County Council with respect to the erection of stands. It appears that in all 1226 applications for licenses to erect temporary stagings to view the procession were received. Of these 1,104 were granted, but in forty-eight cases the licenses were not taken up—ninety were refused, eight were withdrawn, and twenty-four were made too late for them to be dealt with. Two hundred and two structures in various parts of London, consisting chiefly of temporary stands and balconies, were condemned.

The Revue Scientifique draws our attention to the longevity of astronomers. We cannot reproduce their whole list of instances, but it may be interesting to our readers if we mention a few. First in the list comes Fontenelle, who lived just 100 years (1657-1757). Then Caroline Herschel, sister to the great Herschel, who reached her 98th year. Cassini died at 97, Sir Edward Sabine at 94, Moiran at 93, Giovanni Santini and Sharpe at 91. Yates, Airy, Von Humboldt, Robinson and Long each lived to the age of 90. The list of those who lived 80 years is so long that we can only give quite a small fraction of the names. Among them figure Halley, Newton, Herschel, Kant and Roger Bacon.

Writing in the scientific department of the Debats, M. Henri de Parville announces that two investigators, MM. Thomassi and Asselot, have succeeded in obtaining a non-inflammable celluloid. M. Thomassi's invention remains his secret, but M. Asselot has given his discovery to the world without delay. He dissolves ordinary celluloid in acetone in the proportion of 25 grammes of the former to 250 grammes of the latter. Then he dissolves, separately, 50 grammes of magnesium chloride in 150 of alcohol, and forms a paste of the two solutions. When the volatile solvents have evaporated there remains, according to M. Asselot, a celluloid which is absolutely uninflammable. He has, it may be trusted, made no mistake, for there can be no doubt that ordinary celluloid, which is mainly guncotton and camphor, is as dangerous as it is useful.

The importation of petroleum into Trieste in tank steamers has given rise to an Austrian government inquiry as to the vapor of petroleum hanging about the tanks and the dangers arising from the explosive mixtures to which it gives rise, says the American Manufacturer. The result is that a method has been adopted by which the air from various parts of the tank is extracted and subjected to a threefold test—with a eudiometer to see whether there is any diminution of volume on explosion, with a Davy lamp to see whether the flame is altered by the suspected air, and with an open flame to see if it is inflammable, and if so, what kind of flame is produced; and it is only when these three tests are satisfactory that a light can be allowed near the tank. Otherwise, ventilation must be vigorously carried out until there is no explosive mixture in any part of the tank.

SELECTED FORMULÆ.

Puncture Cement.—A recently patented preparation for the automatic repairing of punctures in bicycle tires consists of glycerine holding gelatinous silica or aluminum hydrate in suspension. Three volumes of glycerine are mixed with one volume of liquid water glass, and an acid is stirred in. The resulting jelly is diluted with three additional volumes of glycerine, and from four to six ounces of this fluid are placed in each tire. In case of puncture, the internal pressure of the air forces the fluid into the hole, which it closes. Further details are lacking.—American Druggist.

Hair Dye.—There is no hair dye which produces a durable coloration; the color becomes gradually weaker in the course of time, and the new growth of hair always requires after coloration. Here are some typical formulas in which a mordant is employed:

(1.) Nitrate of silver	½	ounce.
Distilled water	3	"

Mordant:

Sulphuret of potassium	½	"
Distilled water	3	"

(2.)

(a.) Nitrate of silver (crystal)	1½	"
Distilled water	12	"
Ammonia water, sufficient to make a clear solution.		

Dissolve the nitrate of silver in the water and add the ammonia water until the precipitate is redissolved.

(b.) Pyrogallic acid	2	drachms.
Gallic acid	2	"
Cologne water	2	ounces.
Distilled water	4	"

(3.) Nitrate of silver	30	grains.
Sulphate of copper	3	"
Ammonia, q. s.		

Dissolve the salts in ½ ounce of water and add ammonia until the precipitate which is formed is redissolved. Then make up to 1 ounce with water. Apply to the hair with a brush. This solution slowly gives a brown shade. For darker shades, apply a second solution, composed of—

Yellow sulphide ammonium	2	drachms.
Solution of ammonia	1	"
Distilled water	1	ounce.

Black Hair Dye Without Silver.—

Pyrogallic acid	3·5	grms.
Citric acid	0·3	"
Boro-glycerin	11	"
Water	100	c. c.

If the dye does not impart the desired intensity of color, the amount of pyrogallic acid may be increased. The wash is applied evenings, following in the morning by a weak ammoniacal wash.

One Bottle Preparation.—

Nitrate of copper	300	grains.
Nitrate of silver	7	ounces.
Distilled water	60	"
Water of ammonia, a sufficiency.		

Dissolve the salts in the water and add the water of ammonia carefully until the precipitate is all redissolved. This solution, properly applied, is said to produce a very black color; a lighter shade is secured by diluting the solution. Copper sulphate may be used instead of the nitrate.—Pharmaceutical Era.

The firm of Golson & Joure have found a mixture suitable for match heads which, although containing no white or yellow phosphorus, may be ignited by friction against any substance. The proportions are:

Powdered glass	80	parts.
Amorphous phosphorus	10	"
Sulphur	10	"

These are mixed, then is added a solution of 850 parts of potassium chlorate in 300 parts of water and 70 of glue. Lastly, there is added to the paste finely powdered potassium ferrocyanide, 50 parts.—Wiener Gewerbe Zeitung.

Photographic Hints and Formulas.—

From Liesegang's Photographischer Almanach.—(Amer. Photo. Jl.)

Metol-Hydro Developer.—For transparency and lantern plates:

(a.) Water	16	ounces.
Metol	30	grains.
Hydrochinon	30	"
Sodium sulphite (crystals)	240	"
(b.) Water	10	ounces.
Potassium carbonate	120	grains.
(c.) Potassium bromide	1	ounce.
Water	10	"

To develop: (a) 1 oz.; (b.) 1 oz.; (c.) 10 to 20 drops. Can be used repeatedly. Temperature should be between 70° and 75° F. Too cold a developer will not give density, while a warm developer tends to give fog.

A Blue Process.—M. Makahara, at the convention of the Japanese photographers, held in Tokio, exhibited some blue prints of rare beauty. The process by which they were obtained was given as follows: A strongly sized paper is necessary. Dissolve 15 grammes of gum arabic in 110 c. c. of hot water; while hot add—

Tartaric acid	2	grms.
Chloride of sodium	9	"
Sulphate of iron	10	"
Perchloride of iron	15	"

The mixture is applied with a sponge to the paper, the sponge then squeezed out, and the excess of liquid removed—in fact, as much as possible is removed. Printing is a little longer than for albumen paper; the yellow of the sensitive paper turns white in printing. The prints are developed rapidly with gallic acid, then washed and sponged.

THE

Scientific American Supplement.

PUBLISHED WEEKLY.

Terms of Subscription, $5 a Year.

Sent by mail, postage prepaid, to subscribers in any part of the United States or Canada. Six dollars a year, sent, prepaid, to any foreign country.

All the back numbers of The Supplement, from the commencement, January 1, 1876, can be had. Price, 10 cents each.

All the back volumes of The Supplement can likewise be supplied. Two volumes are issued yearly. Price of each volume, $2.50 stitched in paper, or $3.50 bound in stiff covers.

Combined Rates.—One copy of Scientific American and one copy of Scientific American Supplement, one year, postpaid, $7.00.

A liberal discount to booksellers, news agents, and canvassers.

THE CAPTIVE BALLOON IN THE NAVY.

At the recent naval maneuvers at Kiel, Germany, the aeronautic division of the German army went through a two weeks' drill, in which the kite balloon described in our paper some little time ago was used for reconnoitering, being made captive on board a torpedo boat.

We may just shortly remind our readers of the construction of the balloon. By means of an attachment on one end, the body, which is elongated, is kept at an angle to the horizontal. The wind, therefore, catches the slanting lower surface as it strikes a kite. The balloon is provided with an air chamber on this surface which prevents it from giving way to the stress and curving. Lastly, there is the usual kite tail, which is raised aloft by an additional circular balloon. The car is independent of the cable which holds the balloon fast. By all these devices great steadiness is secured, and consequently very exact observations can be made.

To be able to transport the balloon quickly from one place to another, the aeronautic division attached it to a torpedo boat, which, owing to its great speed, answered the purpose admirably. But not only was the balloon conveyed from one place to another by this means. The machinery by which the cable was paid out was even transferred from one boat to another without much difficulty.

Experiments were conducted to compare the range of vision from the car with that obtained on lighthouses. The balloon was sent up off Bülk (near Kiel), where a lighthouse rises 97½ feet above the ground. From this tower one can see fifteen miles around, while from the balloon a strong telescope revealed the whole of the Danish seas, even beyond Copenhagen, while in the east Rügen could be distinguished, and in the west the North Sea was visible. The officers of the army and navy practiced recognizing the different ships which were clearly seen in the Great Belt. It is to be expected that this enlarging of the field of vision will be of great importance in naval warfare, as an early recognition of the enemy is always essential.

Our cut is taken from Illustrirte Zeitung.

TORPEDO BOAT TOWING A BALLOON.

POSSIBLE STEAMSHIP SERVICE BETWEEN NEW YORK AND TANGIER.

Consul Burke sends the following from Tangier, June 21, 1897: In view of the opportunity for developing considerable trade between New York and Morocco if steamers touched at this port, I wrote during the past winter to two New York agencies of steamship lines to the Mediterranean to ascertain if it would not be possible and profitable for the companies to include Tangier in their itinerary. The agents of one of the lines informed me it would not be to their advantage, especially as the larger number of passengers by their line did not care to touch at Tangier. The agents of the other line wrote me they would refer my letter to Messrs. Gastaldi & Company, the general agents at Genoa. I also wrote other parties in the United States, asking them to be good enough to interest themselves in the matter, as I felt sure that if steamers touched regularly at this port both from and to New York it would result in our gaining a strong commercial foothold in this country. Whether my efforts in this direction accomplished anything I do not know. I am rejoiced, however, to be able to report that the steamer Sarnia, of the Atlantic line to the Mediterranean, of which Gastaldi & Company are general agents, is advertised to touch at this port on July 2, en route to New York. I understand this is an experiment only; but there is no doubt in my mind that if we have even a monthly service for a few months it will be found necessary, on account of the increase of trade, to establish a bimonthly service for this port. All interested in getting a share of this market for our manufactured products should give aid and encouragement to the proposed venture, in order to render it a success. I have written Messrs. Gastaldi & Company, of Genoa, assuring them that whatever can be done by me shall be done to aid the undertaking. Now, whatever is shipped to the United States goes by way of England, Germany and France. Whatever is brought from the United States must come through the same countries and must of necessity occupy a much longer time in transit. Probably the freight charges are higher when goods are brought in this roundabout way. If the company decides to have a monthly service for this port, our manufacturers and merchants should put commercial travelers in this field at once with samples of their products. A sample house should be opened, with a man at the head who is active, enterprising and shrewd. He should be a man who knows the country and the people, not only of Tangier, but all the coast towns. The whole of Morocco would be his field, and our people would reap benefit. I sincerely hope that the experiment by the Atlantic Line Company in touching at this port will prove successful for them and beneficial in opening a new channel of trade for us, though it may not be very extensive.

The construction of the line Crampass-Sassnitz on Rugen, Germany, which was completed on May 1, offered several difficulties. In some two miles the trains have to ascend a grade of 97 feet. To make the ascent even it was found necessary to cut into the Crampass plain from Crampass to the sea shore. But a greater difficulty yet had to be overcome in laying the track along the shore, where the whole line had to be protected by a sea wall, the building of which involved considerable expense.—Uhland's Wochenschrift.

A NEW SYSTEM OF THROWING HIGH EXPLOSIVES.*

By Hudson Maxim.

For a generation there has been a race for supremacy between guns and armor, between penetration and resistance, between offense and defense. This race has resulted in the development of cannon of comparatively small caliber, but with great thickness of wall and tremendous weight. In order to withstand the enormous pressures necessary to impart requisite velocities to long and heavy armor-piercing projectiles. Powder space within the armor-piercing shell has been sacrificed to weight and strength of metal, reliance being mainly placed upon the smashing effect of a huge bolt of steel. Opposed to this we find the modern battleship, clothed in a wall of steel so ponderous as to reduce mobility to a minimum.

Now, with the advent of a system of throwing high explosives, in sufficiently large masses to render armor absolutely useless, we shall find navies discarding their armor, and everything will be made subservient to speed and mobility. This will work a complete revolution in the construction of ordnance and ships of war. Heavy ordnance, instead of being made, as at present, of small caliber, with thick and heavy walls, will be made of much greater caliber, and with comparatively thin walls. The projectile which will then be employed will be a thin shell, simply thick enough to support the mass of contained explosive in its flight from the gun; and the explosive will be sufficient in quantity to work infinitely more destruction upon any target than such projectiles as are at the present day thrown from heavy guns.

One of the requisites of primary importance to a system of successfully throwing high explosives in large masses rests upon the propelling charge—upon a suitable gunpowder—one which will give a sufficiently low initial pressure, and maintain that pressure behind the projectile in its flight throughout the entire length of the gun, and a powder which will, with absolute certainty, burn alike at all times under like conditions, in order that predetermined pressure and velocities may be depended upon.

I first began the investigation of the subject of high explosives and smokeless powders in England in 1889. Since that time I have built two powder mills in America, one for the manufacture of high explosives, the other for smokeless cannon powders. In connection with my other work on these lines, I conducted a large number of experiments for the Pneumatic Torpedo and Construction Company, of New York, formerly known as the Zalinski Pneumatic Dynamite Gun Company, looking to the production of a smokeless torpedo powder; that is, a powder for the purpose of throwing high explosives, or aerial torpedoes, from ordnance.

The distinguished chemist Dr. Robert C. Schüpphaus has been associated with me in this work. He is also an inventor, and his extensive chemical knowledge and experience in connection with nitro compounds particularly qualified him for this work.

Owing to the shortness of range of the pneumatic guns, and to the expense, cumbersomeness and vulnerability of the plant necessary to operate them, it was determined, if possible, to substitute gunpowder for compressed air.

How well we have succeeded in the Maxim-Schüpphaus smokeless powder to accomplish the desired results, and the special advantages that this powder has for the purpose, is one of the things which I shall here try to explain.

One of the great advantages of high explosives as an agency of destruction is the impossibility of opposing to them any efficient means of protection, when applied in large quantities. By the subdivision of the hull of the modern battleship into a honeycomb of water-tight compartments, and by surrounding it with torpedo netting, some protection is secured against attack from even the largest of present forms of torpedoes, such as the Whitehead, but the largest and latest type of these will carry but 200 lb. of guncotton. It remains only to be able to attack with a sufficiently large quantity of explosive in order to render absolutely useless as a means of protection all precautions in the form of network and water-tight compartments. Five hundred pounds of guncotton exploded against the torpedo netting surrounding a modern battleship would insure her destruction, to say nothing of what would result from the explosion of still larger quantities.

The nearest approach to the system proposed by me for throwing high explosives that has yet been developed is the system of throwing them by means of compressed air. But the shortness of range of pneumatic guns, the difficulty and expense of protecting them, and the enormous plant of engines, boilers and air compressors necessary, are strong objections to their use for coast defense; while their cumbersomeness and vulnerability, together with the above objections, render their employment on shipboard entirely out of the question.

With the 15 inch pneumatic guns that have been erected in the United States, at Sandy Hook and San Francisco, 500 lb of high explosive may be thrown a distance of about one mile and a quarter; 200 lb. about two and a half miles, this is the maximum range. Hence a battleship could lie just beyond the range of these guns and destroy the entire outfit, without in turn being in the least exposed to the fire of the pneumatic tubes. It is obvious, therefore, that a practical system of throwing aerial torpedoes must have a range substantially equal to that of high-power guns opposed to it, and the quantity of high explosive thrown must be sufficient to effect upon the target greater destruction than can be effected by ordinary shells thrown from heavy ordnance.

Fig. 1 is a sectional view of my improved aerial torpedo and fuse, carrying half a ton of compressed wet guncotton. Fig. 2 is a 12 inch torpedo of the same pattern, carrying 250 lb. of guncotton. The object of this invention is mainly to provide an aerial torpedo projectile which shall carry a maximum of high explosive with a minimum weight of metal, and at the same time be of such constitution, strength, and integrity as to enable it to withstand the shock of acceleration and the pressure of the propelling gunpowder charge, without danger of disruption or distortion of the torpedo, or the premature explosion of it.

* Digest of a paper read before the United Service Institution, London.

The torpedo projectile is preferably made in two sections, a forward and a rearward portion, and joined together in the following manner: The forward portion is made somewhat thicker than the rearward, and the rear end of the forward section is reduced in thickness sufficiently to permit of the two portions being telescoped together, as shown in the drawing. The parts are made to fit closely, and are forced together with considerable pressure, in order to make a very tight joint.

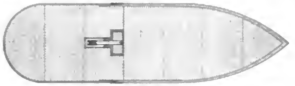

Fig. 1.—MAXIM AERIAL TORPEDO CARRYING ONE TON OF GUNCOTTON.

Fig. 2.—MAXIM AERIAL TORPEDO CARRYING 250 POUNDS OF GUNCOTTON.

To effect the simultaneous rotation of both portions of the torpedo, they are provided with interlocking projections or tongues, and a strong copper driving ring is shrunk or affixed on the projectile at the point of union of the two sections, and overlapping both portions, thus forming an efficient hermetical seal, while at the same time joining the two portions firmly together.

A very suitable high explosive for this torpedo is wet guncotton, previously highly compressed in a series of suitable moulds of proper size and shape, to adapt the cakes or blocks to closely fit a corresponding space in the torpedo. After the torpedo has been filled in the manner described, to such fullness as to prevent the rearward section being forced quite home upon the forward portion, or abutting against the thicker body of the forward section, the two ends are placed together, and the torpedo is subjected to considerable pressure in a longitudinal direction, sufficient to secure the maximum density of the contained high explosive charge. The gas check and driving ring is then affixed in the manner already explained.

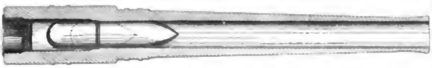

Fig. 3.—SECTION OF MAXIM 46 TON TORPEDO GUN, SHOWING TORPEDOES CARRYING HALF A TON AND A TON OF GUNCOTTON.

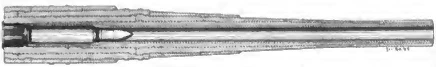

Fig 4.—SECTION OF WOOLWICH 67 TON GUN WITH ARMOR PIERCING SHELL.

When compressed guncotton is used for filling the torpedo in the manner described, its density and unyielding nature cause it to serve as a support to the walls of the projectile and prevent its disruption or distortion under the great pressure of gases of the gunpowder charge, and the sudden shock of acceleration, thus permitting the use of thinner walls than when filled with a more yielding material.

The walls of the forward section of the torpedo are made thicker than those of the rearward portion, in order to give greater weight to the forward end of the torpedo to secure a truer flight, and also such strength as to enable it to penetrate deck armor or earthworks before exploding.

Figs. 3 and 4 illustrate the position of the guncotton torpedo in the gun, as well as its size, compared with other forms of projectiles now in use, thrown from guns of half the caliber, but of greater weight, and of the same exterior dimensions from forward of the trunnions back to the rear of the gun.

The whole of the rearward section of the torpedo projects backward from the driving ring and ring seat into the powder chamber, so that the entire rear portion of the torpedo is surrounded by the gases of the propelling powder charge, which exert their pressure upon it simultaneously on all sides, causing the rearward section to move slightly forward and press hard upon the forward portion, thereby communicating the pressure of the propelling charge to the high explosive contained in the torpedo, which, from its great rigidity and density, is practically incompressible, and prevents the thin shell of the rearward section from collapsing.

It is obvious that inasmuch as the torpedo extends backward beyond the driving ring into the powder chamber, it will be accelerated just so much more by the propelling gases, which give an increased velocity equivalent to a like lengthening of the gun.

The fuse employed is one adapted to explode when the torpedo shall have penetrated to a desired depth in water, earthworks, or the deck of a ship, its action being dependent upon a certain amount of retardation of the torpedo.

Fig. 4 shows, in section, a 67 ton built-up gun of 13½ inch caliber. It shows how it is constructed from sixteen rings or layers of steel, shrunk upon one another. This form of construction and the enormous thickness of wall are necessary to withstand the enormous pressures employed, of 35,000 to 40,000 lb. to the square inch. The gun shown in Fig. 3 is one designed by me for throwing aerial torpedoes. It may be made either from a single casting or a single forged steel tube. You will observe that the diameter of the gun from the rear portion forward one-half its length is the same as that of the 67 ton gun shown in the center, but the caliber of the torpedo gun is 27 inches, twice as great as that of the 67 ton gun; the caliber being doubled at the expense of thickness of the wall, for the two guns, as shown, are of the same exterior dimensions for about one-half their length.

We are enabled to double the caliber, and so materially reduce the thickness of the wall and lighten the

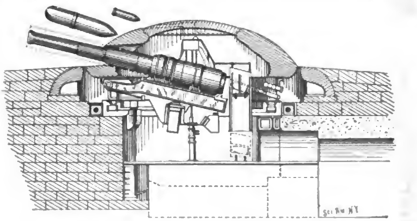

Fig. 5.—ELSWICK TURRET WITH GRUSON CUPOLA MOUNTING.

gun, by simply using a pressure of 10,000 lb. instead of 35,000 to 40,000 lb. This innovation is especially desirable in a torpedo gun, because we do not desire to shoot with an object to penetrate armor, and do not care for a flat trajectory; we desire only an equal effective range to other types of guns, and this rarely.

In the torpedo gun we have a caliber twice as great as in other guns, and consequently have four times the area at the base of one projectile. Therefore, with a projectile of equal weight, we can get a higher velocity with 10,000 lb. to the square inch than can be attained with the high pressure guns employing 35,000 lb. These calculations are based upon the assumption that we have equal length of travel of projectile in the gun, and a pressure in both cases equally well maintained behind the projectile; but we have in favor of this torpedo gun and the torpedo projectile the great advantage that, for a gun of equal length, we get a materially increased length of travel of projectile, and by the employment of a propelling gunpowder charge explained further on, which maintains the pressure practically the same to the muzzle, we are enabled to get a much higher velocity for equal weight of projectile than by the other system.

The projectile used in the British 12 inch wire gun is

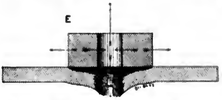

Fig. 6.—AN EXPERIMENT ON THE PHILOSOPHY OF EXPLOSIONS.

three calibers long, and weighs 850 lb. With a propelling charge of 167 lb. 8 oz. cordite, and with a pressure of from 35,000 to 40,000 lb. to the square inch, the projectile is thrown from the gun at a velocity of about 2,350 foot seconds. In the torpedo gun at the top of the drawing is shown a torpedo projectile, carrying 1,420 lb. of picric acid. The total weight of this torpedo will be about 2,700 lb. With a powder charge of 167 lb. Maxim Schüpphaus torpedo powder, and a pressure of 10,000 lb. to the square inch, and with a travel of projectile in the gun of more than seven and a half feet greater than in the wire gun, the torpedo projectile leaves the gun with an enormously greater energy than that of the projectile thrown from the wire gun; but as the projectile thrown from the wire gun has much greater sectional density than the torpedo projectile, it loses less velocity in overcoming atmospheric resistance. However, this is somewhat counterbalanced with the torpedo gun by a higher angle of fire, so that enormous quantities of high explosive can

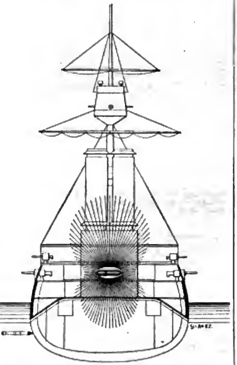

Fig. 7.—EXPLOSION ON BOARD A BATTLESHIP OF THE MAJESTIC CLASS OF A 24 INCH AERIAL TORPEDO.

At lower left is an 18 inch Whitehead torpedo. Black head shows quantity of guncotton carried.

be thrown to a great distance. The torpedo projectile, carrying 1,420 lb. of picric acid, will leave the gun with a velocity of about 2,000 foot seconds, with a range of nearly nine miles. The torpedo enlarged to the dotted lines in front will carry one ton of picric acid, will have a velocity of about 1,500 foot seconds, and a range of about five miles.

The total energy of projection imparted to each torpedo projectile will be practically the same. In the smaller, mass is sacrificed for velocity; in the larger, velocity for mass, so that the total energy of recoil of the gun will be practically equal for each projectile; but as there is somewhat more energy imparted to the aerial torpedo than to the projectile thrown from the wire gun, and as the guns are of equal weight, there will be slightly more recoil to the torpedo gun, but not enough to be a source of any practical difficulty.

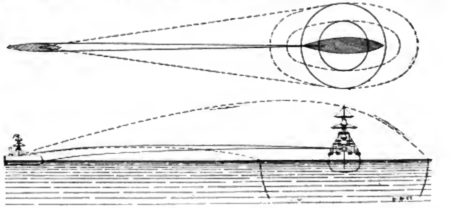
To assist our imagination a little in its realization of the superior destructive energy of these torpedo projectiles above the common armor piercing shell thrown from the high power guns of the present day, I will call your attention to Fig. 5, which is a section through an Elswick turret with Gruson cupola armor.

We can easily appreciate at a glance the superior efficiency of the torpedo projectile as a means of destroying these steel-inclosed bulwarks. The terrible concussion of the explosion upon or against the armored protection, even if it did not totally demolish the steel wall, would certainly throw the gun out of action and

The maximum effective range of the Whitehead torpedo, carrying 200 lb. of guncotton, is less than one mile, and less than one fifth the range of the aerial torpedo carrying eleven times the quantity of high explosive. The efficiency of the aerial torpedo is, therefore, more than fifty times greater than that of the Whitehead.

After conducting a very large number of experiments, Gen. Abbot, of the United States army, estimated a pressure of 6,500 lb. to the square inch, great enough to be fatal to a modern battleship; while Lieut.-Col. John T. Bucknill, in his book entitled "Submarine Mines and Torpedoes," concludes that a pressure of 12,000 lb. to the square inch is necessary to inflict a fatal injury upon the hull of the strongest battleships now made.

Five hundred pounds of guncotton will be fatal, therefore, at a distance of about 38 ft.; maximite and picric acid, about 47 ft.; nitro gelatin, about 54 ft.; one-



Figs. 8 and 9.—COMPARISON OF DESTRUCTIVENESS OF A $500,000 CRUISER WITH THAT OF A $5,000,000 BATTLESHIP.

kill all the gunners, to say nothing of the wreck it would occasion elsewhere, especially on board a battleship. It is hard to predetermine exactly the amount of damage which would be wrought by the explosion of half a ton of guncotton, to say nothing of a ton, upon one of the turrets of a battleship, but the destruction, even though not fatal to the vessel, would be very extensive.

In Fig. 6 we have a very curious illustration, indeed, of explosive energy. A cylindrical body of compressed guncotton, with a hole through the center, was placed on a piece of thin armor plate and detonated; the waves of explosion moving in all directions, as indicated by the arrows, and meeting at the center of the hole, are diverted in the direction of the vertical arrows, with greatly increased density and accelerated velocity, thus blowing a hole through the steel plate directly beneath where the hole was in the guncotton, the plate being simply indented beneath the solid portions of the body of the guncotton.

Fig. 7 illustrates the direction of the action of explosion of an aerial torpedo in its transit across the deck of a battleship. The explosive, being tamped by its own weight, and by the resistance of the surrounding air, will react upon the ship's deck with a disruptive effect similar to that of a torpedo exploded under water adjacent to the unprotected side or bottom of the vessel.

We will now extend our comparisons to other systems of torpedo warfare. Of the many types of torpedoes, the most successful have been the Howell and the Whitehead. The Whitehead, standing in the lead, may, therefore, be taken as the best representative of what has been accomplished in locomotive torpedoes.

half ton of guncotton, about 85 ft.; one ton of guncotton, 108 ft.; while a ton of nitro gelatin would be fatal at 230 ft. As guncotton is the standard service high explosive in this country, I have given special prominence in the table to the destructive range of this substance.

Figs. 8, 9 are intended to illustrate the destructive efficiency of the blast of high explosives as compared with the smashing effect of the blow given by the bolts of steel or armor-piercing projectiles thrown from high power guns.

Fig. 10 gives an enlarged plan view of the deck of the battleship shown in Fig. 9, with numbers showing the areas of the zones of destruction within the circles drawn about the battleship.

The modern first-class battleship costs about $5,000,000. It carries an armament of four 12 in. wire guns, twelve 6 in., and eighteen 3 and 6 pounders, and five torpedo dischargers. Not more than one-half of the guns can be trained upon a single target at one time. Now, at an equivalent expenditure, we can construct and oppose to this ten torpedo cruisers, costing $500,000 each. This sum will construct a very respectable sort of craft, and one which will carry one 24 in. torpedo gun weighing 46 tons, and two torpedo mortars, weighing 20 tons each. The cruiser would fight head on, and the exposed portion could be protected by deflected armor, sufficiently thick to turn aside all shots thrown from a battleship except those from 12 in. wire guns. The torpedo gun would be capable of throwing half a ton of guncotton nearly nine miles, and one ton about five miles. Each mortar will be capable of throwing 500 lb. four miles, half a ton about three miles, and one ton nearly two miles.

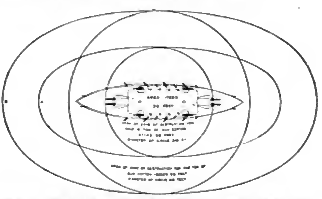


Fig. 10.—DECK VIEW OF BATTLESHIP MAJESTIC, SHOWING DESTRUCTIVE AREA OF AERIAL TORPEDO EXPLOSION.

The Whitehead is a perfect marvel of ingenuity, and the accuracy with which it will travel beneath the surface of the water and strike its target is wonderful. The first torpedoes of this type carried only 18 lb. of dynamite. The quantity of explosive has been constantly increased, and the largest and most powerful to-day carry 200 lb. of guncotton. I will enter into no description of the details or mode of operation of the Whitehead torpedo—a subject so well known—but Fig. 7 will illustrate the comparative sizes of the largest Whitehead torpedo placed alongside one of the 24 inch aerial torpedoes already described, carrying one ton of guncotton.

The tremendous difference in the quantity of explosive carried is very striking, and speaks for the vastly greater efficiency of the aerial torpedo.

The size of the target presented by the cruiser fighting head on would represent an area about equal to her cross section above that portion protected by the water, while the target presented by the battleship to the cruiser would be in proportion to the quantity of high explosive thrown by the cruiser; and to give an idea of what this really means, there is shown on the right a modern battleship, and on the left a torpedo cruiser of the character just mentioned, pictured in the act of firing upon each other. The full lines drawn from the battleship to the cruiser show the trajectory and angle of fire of the battleship, and also within what a limited angle the fire of the battleship must be confined in order to hit the cruiser at all. The dot and dash lines show the angles within which an aerial torpedo carrying a ton of guncotton would be fatal to

the battleship, and the tremendous size of the target presented by the battleship to the torpedo cruiser. At the top of the drawing is a plan view showing the difference in the areas of the decks of the two vessels. Now, the battleship, in order to do any harm whatever to the cruiser, must, of course, make a hit, and to be fatal, that hit must be made in a vital spot, representing an area much more confined even than that represented by the deck of the vessel. As the cruiser would stand and fight with armored head on, the chance of a hit being fatal would be very small; while every torpedo, carrying from half a ton to a ton of guncotton thrown from the cruiser, and striking the area represented by the deck of the battleship, would at least throw the ship out of action, even if it did not sink her. But, in addition to this, we have the tremendous areas within which such quantities of high explosive, striking in the water, would be certainly fatal.

The lines drawn about the area represented by the deck of the battleship show the distances within which different quantities of guncotton would, according to the table, disrupt or crush the hull of the battleship. Half a ton of guncotton, striking anywhere within the space encircled by the line A, would exert upon the hull the required destructive pressure of 12,000 lb.; and one ton within the tremendous area inclosed by the line B. But, as such a blow upon either end of the battleship, although crushing it, would not necessarily be fatal, on account of the transverse bulkheads and watertight compartments, I have drawn about the battleship two circles, representing distances within which half a ton and a ton of guncotton, respectively, falling, would exert upon the hull of the battleship a pressure of 12,000 lb. in such proximity to her vitals as would be certainly fatal.

The cruiser would have a speed of from 20 to 24 knots, and could, therefore, choose her own position with respect to the battleship. Her tactics would not be like the ordinary torpedo boat, to dash into and run a gauntlet of destructive fire from the battleship, to drop a torpedo and away again out of range; but she would stand her ground and fight, always at a distance and in a position of her own choice, with armored head toward the battleship. In such position the target presented by the cruiser would be very small indeed, to say nothing of the difficulty of inflicting a fatal injury upon such a target with ordinary shot and shell.

The fatal area presented by the battleship as a target to half a ton of guncotton thrown from the cruiser is 47,143 sq. ft., and the fatal area presented to a ton of guncotton is 182,925 sq. ft., and it is a very safe estimate that the area exposed by the cruiser fighting head-on would not be more than one two-hundredth as great as the fatal area exposed by the battleship. Now, as every shot from the cruiser striking within the fatal area exposed by the battleship would destroy her, and as it would take a considerable number of hits from the battleship to sink the cruiser, it is very safe to offset the greater number of shots which the battleship could fire within a given time and the horizontal position of the target presented by her by the superior fatality of the shots from the cruiser. This enables us to very easily approximate the comparative efficiency of the two systems, by simply dividing the average fatal area exposed by the battleship by the area of the target presented by the cruiser. Now, as this area is contained in the area exposed by the battleship at least 100 times, one cruiser would be capable of destroying, on an average, 100 battleships. But we can build ten such cruisers for what it would cost to build one battleship, and we must, therefore, multiply this efficiency by ten. This means that we could, for the cost of one battleship, produce a fleet of torpedo cruisers which would be capable of destroying 1,000 first-class battleships.

These are, indeed, astounding figures. They are, nevertheless, based on such foundation in facts as to, at least, warrant our placing them in a category of practical probabilities.

In the choice of a high explosive for aerial torpedoes there are several desiderata, in addition to the mere force of the explosive. In the first place, it should not be so sensitive to shock or percussion as to be in the least endangered by the sudden force of acceleration exerted upon it in the gun. It must be perfectly stable and undergo no change by time and under varying conditions of temperature. It must be perfectly neutral, having no effect upon the metallic surfaces exposed to it. It should have as high a specific gravity as possible, in order to exert the maximum energy per unit volume. There is one more and very important desideratum, not possessed by any other explosive in like degree as by wet guncotton, and that is insensitiveness to detonation, not only from shocks of percussion, but shocks of ordinary forms of explosion. Guncotton can only be detonated by the explosion of a powerful detonative charge in direct contact with it.

Nitro-gelatin is the most powerful of commercial high explosives, but this explosive is too sensitive for employment in aerial torpedoes to be thrown from guns by gunpowder at high velocities.

Maximite is a title which was first applied to a high explosive invented by me and made according to my United States patent No. 544,924. A stiff nitro-gelatin of the character of that just above described, consisting of about seventy to eighty parts nitro-glycerin and twenty to thirty parts of a very soluble variety of gelatin-pyroxylin, soluble in nitro-glycerin below 100° F., is frozen stiff and then cut into sawdust by a gang of saws. About seventy-five to eighty parts of this explosive sawdust is mixed and thoroughly incorporated with about twenty to twenty-five parts of finely pulped tri-nitro cellulose, the whole being saturated with water. The object of the fibrous tri-nitro-cellulose is to absorb and hold water and lessen the sensitiveness of the compound. The compound may be packed into shells to a density of about 1·4, holding about 15 per cent of its weight of water, the excess of the water being poured off.

Projectiles filled with maximite may be thrown from ordnance at service velocities with perfect safety. This compound will detonate under the influence of a strong exploder with all the violence of the original ingredients of which it is composed.

Picric acid is a very powerful high explosive, and when melted and cast it has a specific gravity of 1·7. It is highly insensitive to all ordinary influences and is, therefore, exceedingly well adapted for use in aerial torpedoes.

In view of the highly insensitive character of wet guncotton, and the fact that it is as powerful as No. 1 dynamite, to say nothing of the other high explosives just mentioned, it is hard to see the need of air guns if we have a suitable torpedo powder, by which low pressures can be had and maintained and projectiles with thin walls be thrown with safety.

In making a comparison between the system shown you to-day and that of the best system yet developed for throwing torpedoes by means of compressed air, erected at Sandy Hook and San Francisco, in the United States, it may be noted that the caliber of the largest of these pneumatic guns is only 15 inches, while its length is 50 feet and its weight 70 tons. Its maximum range with 500 pounds of high explosive is about a mile and a quarter. The pressure employed in the gun is only about 1,000 pounds to the square inch—greater pressure than this having been found impracticable.

TESTS OF THE STRONG BALANCED LOCOMOTIVE AT PURDUE UNIVERSITY.

The Strong balanced locomotive, after undergoing successful tests in actual service, was recently sent to the celebrated locomotive testing plant at Purdue University, in order that the results obtained on the road might be corroborated by the more careful methods of the laboratory. This engine, which in its original form attracted more favorable comment from the railroad press than any modern locomotive, has been fully illustrated from time to time in our various publications, and the reader is referred to the SCIENTIFIC AMERICAN and the SUPPLEMENT, respectively for November 14 and 21, 1896, where a detailed description will be found. The following abstract of the report of Prof. W. F. M. Goss, under whose supervision the tests were carried on, is taken from the Railway Age, to which the latter was contributed by Mr. George S. Morison, the vice president of the Balanced Locomotive and Engineering Company.

The locomotive will be recognized as embodying some principles of construction embraced in what was originally known as the Strong locomotive, exploited to a considerable extent over a period of several years beginning with 1887.

Three radical departures from ordinary practice are involved in the construction. These relate respectively to the system of compounding and connecting the valve motion and the construction of the firebox. The last named consists essentially of a pair of tubular shells circumferentially corrugated. The corrugation largely increases the amount of firebox heating surface as well as adding so materially to the strength of the shell that the necessity of staying is obviated. The two corrugated shells which form the firebox proper are brought together at their forward end and united in a single shell, also corrugated, which serves the purpose of a combustion chamber.

The valve motion, which formed a unique feature of the Strong locomotive, has been retained in the present example, but as its working formed no part of the test with which the present report deals, its description is omitted.

The arrangement of the cylinders and connections is not complicated. The two high pressure cylinders are located inside the frames and are connected with cranks upon the shaft. The low pressure cylinders are outside the frames in the position of the cylinders of an ordinary simple locomotive and are connected outside in the ordinary manner. The inside crank of one side is connected at a point diametrically opposite the outside connection upon the same side, and the corresponding cranks upon one side are at right angles with those upon the other side. A full description, with diagrams showing the effect of such construction upon the question of counterbalancing, is contained in Prof. Goss' report, which follows.

A REPORT OF TESTS TO DETERMINE THE CONDITION OF DRIVE WHEEL BALANCE IN "BALANCED COMPOUND LOCOMOTIVE NO. 1." OUTLINE OF TESTS.

In preparation for the tests the engine was mounted upon the locomotive testing plant of Purdue University, which provides: 1, Supporting wheels carried by shafts running in fixed bearings to receive the locomotive drivers and to turn them; 2, brakes mounted upon the shafts of the supporting wheels and having sufficient capacity to absorb continuously the maximum power of the locomotive; and (3) a traction dynamometer to indicate the pulling force exerted by the locomotive wheels. The arrangement of the plant is such that a locomotive mounted upon it may be driven by its own steam at any speed and under any load, the conditions being similar to those of the track.

When the engine had been thus mounted, provision was made for passing lengths of small soft wire under the tread of the drivers while the engine was running at speed, the expectation being that the thickness of the wire as it came from under the wheel would bear some relation to the pressure imposed upon it during its passage. It was thought that if through the action of the counterbalancing, or from any other cause, the pressure of the wheel upon the track should chance to vary as it revolved, the resulting wire would vary in thickness.

That such expectation was reasonable may be inferred from results of similar tests previously conducted in connection with a locomotive which was balanced in a manner now common on all roads. Wires which had been passed under the wheels of this engine not only showed regular variation in thickness, corresponding with definite portions of the wheels' cycle, but when the speed was high, portions of the wire would retain their original section, notwithstanding the fact that they had passed under the tread of the wheel, showing conclusively that the wheel had risen entirely clear of its support during a portion of its revolution.

SUMMARY OF RESULTS.

The results of the tests fully confirm the theory which underlies the design of those portions of the engine affecting the balance of the drive wheels. In the course of the tests wires were repeatedly obtained both from main and rear drivers, while the engine was working at a high speed, which were practically uniform in thickness. A full description of typical wires is given in another portion of this report, and sample wires are submitted. They show that there was little or no variation in the pressure with which the drivers act upon the supporting wheels, and justify the conclusion that the maximum wheel pressure, when the engine is running at speed, is practically no greater than the static pressure due to the weight of the engine; in other words, the so-called "hammer blow," which attends the action of ordinary engines when run at high speed, does not appear in the action of the balanced locomotive.

In discussing the behavior of engines which are balanced in the usual manner, Prof. Lanza, in a paper presented to the American Society of Mechanical Engineers, says:

"There are five different motions which the locomotive (of ordinary type) would receive through the action of the reciprocating parts if free to obey them. They are as follows:

"1. Jerking, or forward and backward motion.

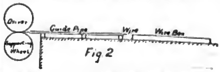
"2. Nosing, an oscillation about a vertical axis through the center of gravity.

"3. Galloping, an oscillation about a horizontal axis at right angles to the track.

"4. Pounding, a vertical up and down motion.

"5. Roll, an oscillation about a horizontal axis."

Without attempting to distinguish between all of these several oscillations, it may be said that experience with testing plants proves that with both eight wheeled and ten-wheeled engines of the ordinary types, running at speed, the jerking is so severe as to make it difficult to hold the engine under test to its position on the plant, while the nosing action results in a side swing of the front bolster through a distance of from a quarter to three-eighths of an inch, depending upon the speed.



METHOD OF INTRODUCING WIRES.

The balanced locomotive, on the contrary, gives very little jerk, and the side swing of its first bolster is not over an eighth of an inch under any condition of speed at which tests were run.

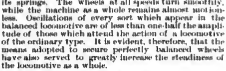
The longer wheel base of the balanced locomotive, as compared with that of the other locomotives referred to, would assist somewhat in holding the engine steady, while, on the other hand, the bolster from which measurements were made is located well out in front of the body of the engine, a position much farther from the drive wheels than that occupied by the bolsters of the engines referred to, and one which makes apparent a very slight angular movement.

The conclusion is, therefore, that whatever the speed, the wheel pressure of the balanced locomotive will not vary except as the wheels may be acted upon by accidental forces, as for example impact due to inequalities in the track or changes in the position of the center of gravity of the heavier portions of the machine relative to wheels, through the engine rocking or tipping on its springs. The wheels at all speeds turn smoothly, while the machine as a whole remains almost motionless. Oscillations of every sort which appear in the balanced locomotive are of less than one-half the amplitude of those which attend the action of a locomotive of the ordinary type. It is evident, therefore, that the means adopted to secure perfectly balanced wheels have also served to greatly increase the steadiness of the locomotive as a whole.

FORM OF END OF WIRE.

A DISCUSSION OF COMMON PRACTICE IN BALANCING DRIVE WHEELS.

In an eight-wheeled locomotive of the ordinary type there are connected directly and indirectly with the cranks on each side, a coupling rod, main rod, crosshead, piston rod, and piston (Fig. 4).



DISTRIBUTION OF WEIGHTS TO BE BALANCED.

When the engine is in motion, every portion of the coupling rod follows a circular path, and the effect of the centrifugal forces resulting from it, which alone affect the balance of the wheels, is the same as would result if its place were taken by weights symmetrically disposed about the two crank pins, each weight having half the mass of the rod.

The main rod has different motions at every different point throughout its length. The crank pin end follows a circular path, while the crosshead end moves along a straight line; the effect of this motion, so far as it concerns the balance of the wheels, being the same as that which might be produced by an imaginary rod, one portion of which is assumed to follow a circular path only, and the remaining portion a rectilinear path only. That is, a portion of the mass of the rod such as that upon the right of the dotted line, A, Fig. 4, may be assumed to be simply a revolving mass attached to the crank pin, while the remaining portion may be assumed to partake of the motion of the crosshead only, of which, in effect, it becomes a part.

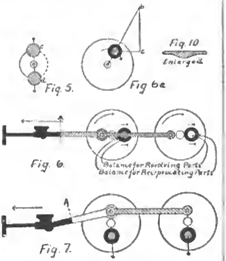
The rotating parts, therefore, which require attention in balancing the drive wheels are the cranks, the crank pins, the coupling rods, and a portion, usually about two-thirds, of the main rod; the reciprocating

parts are a portion, usually a third, of the main rod, the crosshead, the piston rod, and the piston. In Fig. 4 the revolving parts are shaded, while the reciprocating parts are in outline.

A perfect balance of all the revolving parts attached to the pins, and of the cranks and crank pins themselves, may be secured by adding weights to the opposite side of the wheels, the condition for each wheel then being that shown by Fig. 5, in which the masses s and d are assumed to be revolving about the center c, the one representing the masses connecting with the crank pin, and the other the mass of the counterweight. As the centrifugal action of each of these masses is radial, and as the masses are on opposite sides of the center about which they rotate, the system is in perfect balance.

But it is to be noted that all this applies to the revolving parts only. A locomotive in which the counterweights are only equal to the revolving weights (Fig. 4), if used at the head of a train, will act upon the latter by a succession of jerks which will be too severe in their effect to be permitted.

The reason for this will be understood if we consider



ACTION OF EXCESS BALANCE.

the conditions existing in an engine at speed at the instant the cranks are passing the center; that is, when they are in position shown by Fig. 6. At this instant, the radial force exerted upon the crank pin, arising from the motion of the connected parts, is the sum of that due to the rotating parts, plus that due to the reciprocating parts.

To make the engine pass the centers smoothly, therefore, additional weights are put into the wheels, which are shown diagrammatically by the black annular masses in Fig. 6. This portion of the counterweight, which is in excess of that required by the revolving parts, and which is added on account of the reciprocating parts alone, is called the "excess balance."

In the position shown by Fig. 6, the excess balance acts in opposition to the reciprocating parts, and when properly proportioned may hold them in perfect equilibrium; but with a change in the position of the wheel this condition ceases and other conditions appear.

Thus, Fig. 7 shows a change of a quarter of a revolution.

In the new position the action of the excess balance

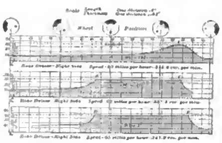


FIG. 8.—DIAGRAMS OF WIRES FROM ORDINARY LOCOMOTIVES.

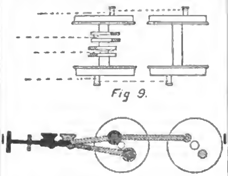
cannot in any way be opposed by that of the reciprocating parts; and hence, its only effect is to increase the force with which the wheel presses upon the rail.

To make the statement of the whole matter a trifle more technical, but vastly more comprehensive, it may be said that since the counterweights move in circular paths, it is only the horizontal component of the radial force derived from them which can serve to neutralize the effect of the reciprocating parts; the vertical component of all that portion of the force which applies to reciprocating parts, that is, of the excess balance, is unbalanced. This unbalanced vertical component causes the pressure of the driver on the rail to vary with every revolution, its changing value being well illustrated by Fig. 6a, in which a b is the radial force, a c the horizontal component and b c the vertical component, resulting from the rotation of the counterweight about the center o. If the counterweight revolves at a uniform speed, the radial force will be constant, but the value of the components a b and a c will constantly vary, one increasing as the other diminishes.

The Purdue experiments were conducted in a manner similar to those made in connection with the balanced engine already described, and a detailed description of them is presented as an appendix to this report. Fig. 8 gives the actual thickness of some of the wires at different phases of the wheel's motion.

As the result of theoretical research, observation upon the road, and of laboratory investigation, the destructive effects upon track and bridges arising from the presence of the excess balance is now generally recognized; but, notwithstanding this there have been as yet few attempts to abolish the excess balance, which is the root of the evil. The fact still remains that an engine of the ordinary type pulls its train most smoothly and rides the easiest when the excess balance is equal to the full weight of the reciprocating parts. A common rule allows the excess balance to be equal to 70 per cent. of the weight of the reciprocating parts, and requires that it be equally distributed between the coupled wheels. The present rule of the American Master Mechanics' Association requires that one four-hundredth part of the weight of the engine be subtracted from the weight of the reciprocating parts of each side to find the weight of the excess balance, which



CONNECTIONS OF THE BALANCED LOCOMOTIVE.

must be divided equally among the coupled wheels on each side. If applied to most engines now running, this rule would give substantially the same results as the first one stated; but for the very heavy engines now built, it allows a larger proportion of the reciprocating parts to go unbalanced; a practice which is justified because of the ability of the heavier machines to absorb the oscillating forces developed by the motion of the reciprocating parts before they can be transmitted to the train.

There has been no lack of effort on the part of superintendents of motive power to make locomotives of the ordinary type less destructive to track, but it is very doubtful if all that has thus far been done has accomplished more than to prevent a growth of the evil, as engines have been increased in size and speed.

THE PRINCIPLES UNDERLYING THE DESIGN OF THE BALANCED LOCOMOTIVE.

Referring to the mechanism of one side of the balanced locomotive, there is outside of the frame a low pressure cylinder, the reciprocating and revolving parts of which connect with crank pins in the usual manner. These parts are shown in black in Fig. 9. Inside of the frame, and as close to the low pressure cylinder as practicable, is a high pressure cylinder, the revolving and reciprocating parts of which connect with an inside crank. It is to be noticed that the inside crank is diametrically opposite to the outside crank.

By the arrangement described, all revolving parts are balanced by revolving weights, and all reciprocating parts by reciprocating weights. The following is a description of the manner in which this is accomplished: The rear wheel has only revolving parts connected with the crank pin, and the counterbalance in this wheel is made sufficient for these parts alone. As there is no excess balance in this wheel, the condition of perfect equilibrium is maintained undisturbed.

While the conditions affecting the main wheel are somewhat more complicated, they are nevertheless quite as perfectly dealt with. The revolving parts (Fig. 9), attached to the outside crank pins, are perfectly balanced by the revolving counterbalance in the wheel, and the reciprocating parts attached to this crank pin have absolutely no balance in the wheel. Again, the revolving parts attached to the inside crank are perfectly balanced by revolving parts attached to these cranks. The reciprocating parts connected with the inside crank have no balance in the wheel. That is, the revolving parts attached to the crank pins are in each case balanced by revolving counterweights, which enter into the design of the wheels and cranks. The main wheel has no excess balance.

The reciprocating parts connecting with the outside crank pin are unbalanced, so far as this crank pin is concerned, and the similar parts connecting with the inside crank pin are unbalanced so far as the crank pin is concerned; but these two unbalanced elements are designed to be equal, and, being connected with crank pins which are diametrically opposite, their motion is opposite, and hence they hold each other in equilibrium. One is a balance for the other. As, therefore, the reciprocating parts are completely balanced, there are no forces to "jig the train," and as no use is made of "excess balance," there is no "vertical component" to act upon the wheel and to vary its pressure upon the rail.

These statements are based upon the truth of the principle which appears to be fundamental in the design. As the actual weight of the parts involved is not available, the statements cannot be demonstrated numerically, but the tests already described go to indicate that, having adopted a correct principle, the designer made no mistake in the development of details.

THE EXPERIMENTS.

In carrying out the experiment with the balanced locomotive some difficulty was experienced in guiding the wire between the driver and its supporting wheel—a difficulty due to the fact that the treads of the drivers were coned, while the face of the supporting wheels were straight, the line of contact between them, as measured across their face, being, as a consequence, very short. For this reason it sometimes happened that a wire, which had been started, would roll out from under the wheel, either partially or entirely, and thus present a variable thickness. It is evident, however, that irregularities resulting from this cause would occur at random; that is, they would have no definite relation with definite phases of the wheel's motion, and in making comparison all such wires have been thrown out.

A defect of another sort also appears in some of the wires. It happened that the wires which were first used proved to be so hard that they impressed themselves slightly into the face of the wheels. Wires, which were afterward sent through, occasionally followed at intervals along their length the very slight grooves which the previous wires had formed, and when this occurred the wire is flattened less than at other portions of its length. But there is no occasion for false conclusions from this cause, since in every case the impress of the groove is clearly traced upon the wires, sections containing this defect being similar to that shown by Fig. 10.

THE WIRES.

In the course of the experiments a large number of wires were run under the several wheels experimented upon. Many of these were calipered at 2 inch intervals throughout their length and the dimensions thus formed were plotted to scale.

[The plotted thicknesses of 16 of these wires are given in the report, and the actual wires accompany the report as appendices. The appendices include the following: Wires obtained while the engine was running at a speed of 38·1 miles an hour (190 revolutions per minute); wires obtained while the engine was running at a speed of 49·5 miles an hour (247 revolutions per minute); wires obtained while the engine was running at a speed of 53·9 miles an hour (269 revolutions per minute); wires obtained while the engine was running at a speed of 60·1 miles an hour (299 revolutions per minute); several copper wires, all from the left forward driver, obtained at speeds which were between 55 and 60 miles per hour. In explanation of the comparative diagram, Fig. 11, the thickness of the wires is represented by the distance of the heavy sinuous line from the base, the distances being 50 times greater on the diagram than in the actual wires. The thickness of the wire as plotted as compared with its length as plotted is 600 times greater than the thickness of the actual wire is to the length of the actual wire. These proportions have been chosen for the purpose of exaggerating on paper the variation in the thickness found in the actual wire.—EDS.]

The significance of the results already described is emphasized by comparing them with results obtained in similar manner and under similar conditions from an engine of the ordinary type. Such a comparison is made in Fig. 11. The diagram of the wire from the balanced engine, which appears in this figure, is not shown elsewhere, but that of the wires from the ordinary engine is taken from Fig. 8, changed in scale and as to the direction of wheel motion.

The diameter of the drivers for the balanced engines is 67·4 inches, and for the ordinary engine 62·5 inches, so that while the number of revolutions per minute for the latter is somewhat greater than for the balanced engine, the speed in miles per hour is less. These differences, however, are too slight to impair the value of the comparison. The original wires were, in both cases, of practically the same size.

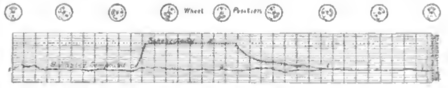


FIG. 11.—COMPARISON OF WIRES TAKEN FROM LOCOMOTIVES SCHENECTADY No. 1 AND BALANCED COMPOUND—DOTTED LINE SHOWS ORIGINAL DIAMETER OF WIRES.

The one important difference in condition is to be found in the fact that the wheel of the ordinary engine carried 400 pounds excess balance, while that of the balanced engine, as already explained, had no excess balance. The result is that while the wire from the balanced engine is nearly of the same thickness throughout, that from the ordinary engine increases in thickness as the counterbalance in the wheel approaches the upper quarter, until its full diameter is reached; a condition which continues through several feet of its length, and makes plain the fact that the wheel must have risen clear of its support during a considerable portion of its revolution.

The conclusions already recited seem, therefore, to be fully justified by the data upon which they are based, which conclusions are, in effect, that the drive wheels of the balanced locomotive are at all times in perfect balance, that they neither increase nor diminish the pressure with which they act upon the rails as they revolve, except as they may be acted upon by accidental

causes; and that all the oscillations of the locomotive are very much less than those which attend the action of a locomotive as ordinarily balanced.

THE STRENGTH OF LADDERS.*

To those who spend a dozen hours a week underground, as well as to the miner with his ten hours a day, the strength of ladders is of great interest, and on occasion may become supreme. To quiet apprehensions on this score, and to furnish a basis of judgment as well, the following tests were made, and if any excuse for them be called for, on the ground of crudity or incompleteness, it will be amply given if others, with better facilities for such tests, be persuaded to take the question up.

The ladders tested were of the common "Bull" pine of the Sierra region ("black pine," Pinus Jeffreyi), the sides of 2 in. × 4 in. rough lumber, fairly clear, and the slats of 1 in. × 4 in. nailed on and not notched in. The width of the ladder and the length of step were 12 in. In such a ladder, when new, the strength of the slats would exceed the resistance of the nails, so that it would fail by the pulling off of the slats. Assuming a vertical position for the ladder, the maximum angle of a man's arm in climbing would be included by 45° out from the vertical, which would also represent the maximum tendency toward pulling off to which the slats would be subjected. In accordance with these premises, the tests were made by placing the ladder at an angle of 45° against a support, with the slats on the lower side, and weighting the slats to the point of rupture or detachment by means of steelyards. The results are shown in the table.

TABLE OF LADDER TESTS.

Ladder.	Age, years.	Condition of wood.	Nails, 12 penny.	No. of tests.	Weight of cubic foot of wood.	Pull. Max., lb.	Pull. Min., lb.	Pull. Av., lb.	Remarks.
A	New	Green	Wire	3	24·6	886	600	725	Slats all pulled.
B	"	"	Cut	3	24·6	1,534	1,075	1,324	" " "
E	½	Very wet	Wire	6	23·2	933	612	750	3 slats broke with warning. 1 " " without warning. 2 " pulled with warning.
C	1	Wet	Cut	5	22·6	1,101	811	979	3 slats broke with warning. 1 " " without warning. 1 " pulled with slight warning.
D	1	Damp	"	7	23·1	1,188	356	721	5 slats broke without warning. 1 slat pulled with warning. 1 side broke " "
G	1	Very dry	Wire	6	25·3	464	226	310	All pulled with warning from 2 to 30 seconds.
F	5	Dry	Cut	2	21·7	663	403	584	1 slat broke without warning. 1 " " with slight warning.
F	3	"	"	3	21·7	1,227	709	987	Made on three-year-old slats on same ladder. 1 slat pulled without warning. 1 " broke " " 1 " " with "
G	1	Very dry	Wire	4	25·3	1,345	1,082	1,248	Made on slats pulled from G. All broke without warning.

Before proceeding to discuss the general strength of ladders as brought out, it will be found interesting to compare tests A and B, made on ladders of identical condition, save in the kind of nails used. The relative resistances of the two kinds, wire and cut, was found to be practically in the proportion of their respective adhering surfaces. Twelvepenny wire nails, 73 to the pound, present an adhering surface of 0·785 sq. in. each, the point being ignored and 1 in. being subtracted from the length to allow for the thickness of the slat. Twelvepenny cut nails, 47 to the pound, with the same allowance present 1·394 sq. in. each. Their relative resistances are 725 and 1,324 lb. for 6 nails, or 121 and 221 lb. per nail, which reduces to 154 lb. per sq. in. of adhering surface for wire and 159 for cut nails.

In studying the table, the column of "Minimum Pull" is the one to which the most interest attaches, and in that the smallest value is 226 lb., corresponding also to the smallest average of 310 lb. The descriptive data for this test, G, are "one year in use in very dry place" and "nailed with wire nails." These would seem to be the ear marks of the poorest ladder. Referring to the last test in the table, it will be seen that the wood was sound, but brittle from its dryness. The failure of this ladder was due to the shrinking or drawing away of the wood from around the nails. Shrinking produces also the same appearance, and to a certain degree the same effect, as if the nails had started from their places; the shrinking of the slat is toward the nail head, which is grasped by the wood, and that of the sides is away from the slat against the resistance of the nail point. And this gives an obvious means of diagnosing this malady of extreme dryness, and one that can be applied instantly to any ladder.

But the case is different for ladder D, probably the most dangerous, if not the weakest one of the lot. A minimum pull of 356 lb., and five slats breaking with no warning, make a very dangerous combination. Casual scrutiny, such as one would naturally give to his surroundings on ascending an unfamiliar ladder way, would reveal the weakness of G, but not of D.

From general appearance F would have been classed as the weakest ladder of the lot, so that its record is surprising, and it is quite worth bearing in mind that prolonged dryness is not the worst condition for timber. Returning to a further consideration of D and G, we should also note that taking into account the foot pressure, G is probably as strong as any in the list. In an average man the chord of his arm, bent in climbing, measures 30 in. from center of shoulder to palm of hand, and 60 in. is the distance from center of shoulder to ball of foot. With the foot placed 72 in. below the hand, the pull of the hand is [illegible] of his whole weight, and the thrust of the foot [illegible] of it. With an assumed weight of 200 lb., the pull and thrust are 35 and 166 lb. respectively. On this basis G presents, as factors of safety, 4 for pull and 6 for thrust; D, on the other hand, presents 6 for pull and 2 for thrust, with the additional danger of no warning before rupture. When we come to inclined ladders, the danger of pulling off becomes less, and G drops from the dangerous list.

The points that stand out from the foregoing are three: The weaker ladder is the very dry one; the most dangerous ladder is the damp one; the strongest ladder is the new one put together with cut nails. As a whole, the study is reassuring, and goes to account for the infrequency of accidents from the failure of ladders. As a corollary the following may be suggested: For dry places use dry lumber and notch the slats in flush; for damp places make heavier slats.

* Written for the Engineering and Mining Journal by Robert Gilman Brown.

THE AUTOMATIC IGNITION OF GAS.

In commenting on this subject the Journal of Gas Lighting says that devices of various kinds for automatically lighting gas burners have been introduced from time to time; and in a recent number of the Journal fur Gasbeleuchtung, the chemist of the Berlin Gas Works, Herr H. Drehschmidt, has described the more successful of them. He begins by pointing out that the facility with which an electric lamp is ignited and extinguished has been one of the most prominent advantages of electricity over gas for lighting purposes; and he says the stress of competition has compelled attention to appliances for placing gas on an equality with electricity in this respect. It is probable that electricity will eventually come to the aid of gas; but the electrical devices for igniting gas automatically have so far been either large and ugly, or else complicated, and therefore unreliable. Other appliances are at present simpler and cheaper.

In the apparatus devised by Duke, he took advantage of the well known property possessed by platinum sponge of glowing in a current of hydrogen and air. Coal gas contains as great a volume of other constituents as of hydrogen; but these do not excite the sponge. In a mixture of hydrogen and air, the sponge glows with sufficient intensity to ignite the gas; but it does not ignite a mixture of coal gas and air. Rosenfeld showed, however, that coal gas and air caused the sponge to glow to a certain extent, and that a platinum wire attached to the sponge could be thus warmed. It was then raised to incandescence by the gaseous mixture, which it ignited. Rosenfeld's discovery was comparatively useless, because the sponge was found to become dense and inactive by repeated use. Duke, however, made a preparation of platinum to which this objection did not apply. He saturated meerschaum or similar porous material with a solution of platinum chloride, and dried it in a stream of hydrogen or coal gas at a temperature not exceeding 212° F. The platinum was thus reduced and deposited in a very finely divided condition on the material. It may be parenthetically remarked that platinized pumice, similarly prepared by the reduction of platinum perchloride, is well known in this country by users of Harcourt's method of estimating sulphur in gas. Porous material thus coated with platinum, used in conjunction with a projecting thin platinum wire, made a very durable and efficient appliance for automatically igniting a flat flame burner as soon as the gas tap was turned on. A little care was needed in attaching the appliance to the burner in such a position that it was exposed to the mixture of gas and air; and consequently careful handling was necessary to prevent derangement. But with moderate attention, this appliance remained operative for a long period. Ammonia and sulphureted hydrogen and vapors of carbon disulphide temporarily destroyed its activity.

The appliance was not so readily adapted to incandescent gas burners, and the first attempts to utilize it were unsuccessful. If it was suspended from the rim of the chimney, or attached to the top of the mantle fork, so that it was immediately above the mantle, it was subjected to the action of the hot gases from the flame, and was injured thereby. If placed above a pilot jet at the side of the mantle, some means of extinguishing the jet as soon as the burner was lighted was needed; and a tap which provided for this required in practice such careful manipulation that its general employment was out of the question. It was essential to success that a simple turn of a tap should complete the operation; and the patent taken out by the Greek Canellopoulos, which has been acquired by a company in Berlin, first described a means of accomplishing this result. According to the specification, an abstract of which recently appeared in the Journal, the flame of the burner heats a solid, liquid, or gaseous body in such a manner that the supply to the pilot jet is thereby automatically cut off so long as the burner itself is in use. One method of achieving the object of the inventor was to take advantage of the expansion of a confined volume of air in a tubular chamber set up near the mantle. The lower end of the tube was sealed by mercury, and the expansion of the confined air by the heat of the burner flame forced the mercury up the small gas pipe which fed the pilot jet, and thus cut off the flow to the latter. The supply to both burner and jet was controlled by one tap, and therefore on opening the latter the gas flowed to both simultaneously. The pilot jet was ignited by means of Duke's device, as described for flat flame burners; but before the flame could be communicated to the burner, a considerable quantity of gas had flowed out, and formed an explosive mixture within the chimney. The ignition of this mixture by the pilot jet injured the mantle.

It was therefore necessary that the gas should only begin to flow to the burner after the pilot jet was already ignited by means of Duke's appliance. The firm of Ludwig Loewe & Company made an improved apparatus, also depending on the principle of expansion as set out in the patent of Canellopoulos. They, however, used a platinum wire in place of confined air as the expanding body. The platinum wire was suspended from a hook alongside the mantle, and adjacent to the flame of the pilot jet. Its lower end supported one end of a lever, the other end of which was attached to the plug of a two-way valve on the gas pipe. When the wire was cold and taut, the plug was held so that it closed the way to the burner, and left open that to the pilot jet. If then the gas tap was opened, the gas only flowed to the pilot jet, and was there ignited by Duke's device. Then the heat of the flame of the jet slightly expanded the platinum wire, and thus the way to the burner was slightly opened. The gas which then flowed from the burner ignited from the flash light, and the heat of the burner flame farther expanded the wire. The way to the burner was thus opened to its full bore, while that to the jet was completely closed, and the light extinguished. This appliance, of course, depends for primary ignition on the proper action of the platinized meerschaum and the platinum wire as used by Duke; and it therefore fails with oil gas or other gas that contains little free hydrogen.

After the extinction of the burner, a short time must elapse before re-ignition is attempted, as it is essential that the platinum wire which operates the valve should be cold when the gas is first turned on. On account of the slow flow from the pilot jet, the distance from the tap to the burner or burners supplied should not be more than about 25 feet. If it is more, the interval of time between turning on the tap and ignition is very great. One tap may control several burners, provided each is fitted with the device for automatic ignition.

AMERICAN HORSES FOR GERMANY.

The following has been received from Vice-Consul Sonon, dated Hanover, June 1, 1897:

For about two years, efforts have been made to introduce American horses into Germany. At first great difficulties had to be overcome. The accommodations on the ships were not good; a large percentage died during the voyage, and the rest arrived in such bad condition that the whole lot had to remain in quarantine for several weeks. The freight and other expenses of transportation were high, and last, but not least, the horses were not the kind needed in Germany and hence were not sold at profitable prices. Now, however, some ships of the Hamburg and Bremen lines are fitted out expressly for this service. The freight is lower—$25 per horse, I am told—and the man attending the horses is taken over and returned free of charge. The accommodations are so perfect that the horses arrive here in good condition. The loss on the voyage is reduced to from 2 to 4 per cent. The result is they are permitted to be landed without quarantine. The number of horses sent to Hamburg is much larger than the number sent to Bremen. The unloading at the former port is more convenient, as they can go from the ship directly to the pier, while in Bremerhaven or Nordenhamm, the ports for the larger Bremen steamers, the horses have to be lightered ashore.

The American horses which sell most readily in the German market are thickset working animals of the Percheron breed, with short, specially heavy legs. Until lately, this variety was mostly imported from Belgium. The home demand there, however, has become so great that horses of full growth are at once bought, leaving only young colts to be exported. Danish horses, large numbers of which are imported into Germany, are used for tramways and stages; they are not so heavy as the Percheron breed.

The hoofs of the American horses lately imported are pronounced better than those of the Belgian horses.

Buyers of American horses have made two complaints: They say that the animals, not being accustomed to the food generally given to horses in this country (oats and wheat bran), lose flesh, and that it is several months before they are again in good condition. If American breeders who intend to export horses to Germany should feed the animals some months before they are shipped, as well as on the passage, with oats instead of corn, the animals would remain in good condition. Buyers further complain that the majority of the horses are not broken to harness.

American horses have been sold here lately at prices ranging from $225 to $300 a head.

The demand in Germany is, next after the class above named, greatest for showy, high-stepping horses, in contrast to the American fast trotter; the supply has of late come from Hungary.

Hanover at one time was pronounced to be the best horse market in Germany. It has since lost that standing, though it would be well for importers by way of Hamburg or Bremen to keep an eye on this market.

Army horses are almost exclusively raised in Germany, being bought when young—two to three years old—and kept in the several supply stations (Remonte-depots) until fit for service. They are regarded as needing at that age a special diet; the training, on the other hand, is given in the various regiments, a year or somewhat less being allowed for this purpose.

ENGINEERING NOTES.

Stiffened cement has been used successfully in the construction of a boat by an Italian named Gabellini. The frame is of steel bars a third of an inch in diameter, over which is spread a wire netting. On this the cement is laid and the outer surface is polished. The boat is heavier than one built of wood would be, but is cheaper and slips better through the water. Experiments have proved its strength.

The following are the compositions of some of the most prized of the Japanese copper alloys: 100 parts of copper with from 1 to 10 parts of gold constitute the varieties of shadko, which is colored bluish black with copper sulphate, alum and copper oxide. The gray quisibuishi contains, besides copper, some 30 to 50 per cent. of silver. Sinchu, the best Japanese brass, consists of 100 parts copper, 50 parts zinc, and lastly a bell metal is made up of 100 parts copper, 15 parts zinc, 40 parts tin, and 5 parts of iron.—Prometheus.

The three new steamers built for the Japanese line Toyokisen Kaisha by English shipbuilders are of a construction hitherto unknown in Eastern Asia. They differ from the twelve boats building now for the Nippon Yushee Kaisha in this respect, that they are passenger boats, while the twelve are freight steamers. The speed of the three new steamers is to be 17½ knots per hour, so that they will be faster than the boats of the Canadian Empress line, to the present time the fastest and most comfortable line in those seas. The journey across the Pacific will take twelve days, as against seventeen, which is the present length of the trip.—Uhland's Wochenschrift.

The following paragraph seems familiar—rather more familiar than the steel: We know that "wootz," or Indian steel, was one of the items of the tribute paid by Porus to Alexander the Great. This much prized metal the patient Hindu still produces by his primitive methods, and in a crucible no larger than a chimney pot, over a rude clay furnace fanned by a goat skin bellows, fuses from the ore a small "bloom," or lump of steel, of a quality unattained by European metallurgy. The fuel used is very pure charcoal, and in the crucible is put some chopped wood of Cassia auriculata with green leaves of Convolvulus laurifolia and of the ak or mudar (Calotropis gigantea), a large Asclepiad. Thus was produced the raw material of the famous Damascus sword blades, and from it native armorers still forge weapons of the finest temper, and possibly drills as hard as Mr. Maxim's.—Delhi Morning Post.

The English firm Armstrong & Company has built to order of the Russian government a powerful steamer of peculiar construction. It is intended to ferry passengers and freight of the Trans-Siberian railway over the Baikal lake. Since that lake is covered with ice several feet thick during a considerable period every year, the boat is built so as to be able to break through the ice. At the beginning of 1896 the order was given, and in June of the same year the hull of the vessel was already completed and taken apart again for transport. This undertaking is unique in its kind—a ship of 4,200 tons built in less than six months, taken apart, packed on an ocean steamer, and sent to St. Petersburg. From there it was transported to the terminus of the Siberian railroad, and thence to its destination by sledge. The putting together of the boat was superintended by an engineer appointed by the Russian authorities, and acquainted with the art of shipbuilding.—Uhland's Wochenschrift.

The resistance to fire offered by wrought iron pillars recently engaged the attention of a commission appointed by the Hamburg Senate. The report just issued states that such columns withstand fire very imperfectly, their stability being quite destroyed at a temperature of about 600° C., and the advantage of filling them with concrete is very slight. The case is, however, far different with outer coatings of refractory or non-conducting materials, which have proved capable of protecting the metal from a dangerously high temperature during a certain space of time, and, consequently, of affording effective protection against fire. The substances which appear to have exerted the best effect are the cork composition of Herren T. Gautzweig und Hartmann, and xylolite incased in sheet iron, which substances give out inflammable gases for two hours and a half, leaving a carbonaceous residue that is not destroyed by the steam from the fire hose. A pillar thus coated only gives way after being exposed to the fire for four hours, while seventeen minutes suffice to destroy it if uncoated when similarly heated. Next to the above named substances comes the Monier concrete, laid on in a coat of 1½ inch thickness, which preserves iron for nearly two hours and a half, while plaster of Paris and asbestos cement only gave poor results.—Invention.

The story of a remarkable engineering feat in California is told by the Chicago Railway Review. A great section of mountain was recently torn off by 10,000 pounds of powder, lifted several feet straight up and then pushed bodily forward 40 or 50 feet, tumbling over the gorge below the dam and then falling with an awful roar 125 feet, to remain hereafter for all time as the bulwark of the great dam being built to impound water for the city of San Francisco. The dam is 43 miles east of the city. For two months or more preparations had been made for the monster blast, in common with another blast that is nearly ready. The plan was to cut tunnels into the side of the mountain at various points above the bed of the creek and to place in these tunnels first great stores of black powder, which ignites slower than giant powder, and, therefore, it has more pushing power and less shattering effect. On the surface and in places through the mountain side were placed big deposits of giant powder for the purpose of shattering the mass and lifting it up. According to plans, the black powder when it exploded would hurl the mass straight forward, making a bridge of granite across the gorge and blocking the stream. The plans were carried out with the greatest care and with a successful result. When the dust cleared away, it was found that the blast had dislodged a mass of rock 400 feet up and down stream and an average of 60 feet in height, completely bridging the canyon. The engineers estimated that the amount dislodged weighed about 150,000 tons. The rock was thrown exactly as the engineers had planned.

ELECTRICAL NOTES.

The steam tramway from Cassel to Wilhelmshöhe has been bought by Siemens & Halske, and is henceforth to be replaced by electrically propelled cars.—Uhland's Wochenschrift.

An improvement that should prove useful on diving dress is a telephone transmitter attached to the helmet, placing the driver in direct communication with his helpmates above.—Revue de l'Electricité.

A second submarine cable was laid from England to France on May 8. It strikes the British shore west of Dover, and France west of Calais. A third cable is going to be laid by the French Government.—Revue de l'Electricité.

In England the total number of subscribers on the telephone lines was 8,000 in 1885, and increased to 13,000 in 1886. In the same year fifty-nine supplementary offices have been opened, and the total number of communications has risen to 350,000,000.—L'Electricien.

In July of this year boats propelled by electricity were experimentally run on the Spree, at Berlin. The elegant boats are built by the Hagener Accumulatorenfabrik, and carry 30 passengers. They effect a communication between the Exchange and the Richard Wagner Strasse. There will be five stopping places, and the whole fare will be 10 pfennig, i. e., about 2½ cent.—Uhland's Wochenschrift.

A writing pen provided with a small electric lamp has lately been patented in Germany and Austria. By this device it is said that the paper in front of the writer is kept well lighted, the disagreeable shadow of the pen being altogether done away with. The invention would scarcely seem simple enough to come into general use; how such a pen would work in the dark can be found out by trial only.—Wiener Gewerbe Zeitung.

The Russo-Belgian Electrical Company has recently obtained, jointly with the Helios Company, of Cologne, and the Russian Lighting Company, at St. Petersburg, the sole right of laying in the Russian capital cables for supplying private houses with electricity for lighting purposes. This concession implies enormous privileges. The share of the Belgian company alone comprises the installation of 100,000 lamps.—L'Energie Electrique.

In fairly strong rain the moistened surface of the earth may be used as a conductor for telegraphic purposes; a double conducting system, i. e., a whole circuit, may sometimes be obtained by using for one conductor the surface moisture, and for the other the well water under ground. It seems, however, the experiments made in this direction can have no practical application, as the connection can only be used under rare circumstances.—Prometheus.

A block signal system has been tried in the great thoroughfares of London (England). The contrivance consists of a high mast, on which the police officer in charge may at will hoist a sign with the word "stop." At night the signal is lighted by electricity. The arrangement is simple, and seems to work very well. It ought to prove very useful not only in preventing dead-locks in the traffic, but also in opening a path for fire engines and public processions, etc.—Uhland's Wochenschrift.

It has often been noticed that high chimney stacks are only rarely struck by lightning. By statistics, such exceptional cases occur three times in 10,000, while steeples are struck 60 times, windmills even 80 times out of the same number of cases. The fact is explained by the discharge which the ascending smoke continually keeps up. In some places it is customary to light a big fire on the approach of a thunderstorm. The origin of this may lie in the same quarter.—Der Stein der Weisen.

At the Victoria Station, Manchester, England, baggage to the weight of 1,500 lb. is transported by a combination of suspended electric cars and electric elevators. The work is done with wonderful rapidity and has, so far, led to no accidents or disorder of any kind. On account of its simplicity, speed and safety this system should prove extremely useful, and worth being adopted in other places where heavy weights are transported over short distances.—Monatschrift für Oeffentlichen Baudienst.

The lead fuses of Fischer Hinnen recall the magnetic blow-pipe and the lightning arrester of Siemens & Halske, which quickly interrupts any arc. According to the description, apparently by its inventor, in Eclairage Electrique, the fuse wire is wound in the deep grooves of a porcelain bar; the grooves are sharp-cornered, and have a depth of one inch. The porcelain is hollow, and contains a soft iron core with pole plates above and below. At the lower extremity is a terminal from which the spiral lead wire starts; the other end of the lead wire is attached to the upper plate, so that the current returns through the iron core and the pole plates. A long fuse can thus be applied, and the winding of the wire around, though in series with the iron core, makes the iron an electro magnet, which blows out any arc formed. The one test mentioned is not particularly convincing, but the fuse, if not too heavy and cumbrous, may well answer its purpose.

The following statistics, giving the number of motors connected to the mains of the Berlin Electricity Works, have just been published, says The Engineer: In all 1,098 motors are connected, aggregating 6,110 horse power. Of these, 372, corresponding to 1,379 horse power, work presses; 333 motors, or 1,900 horse power, are used for lifts; 226 motors, or 177 horse power, for ventilators; 196 motors, or 645 horse power, for machine tools for metal working; 77 motors, or 311 horse power, for woodworking machines; 74 motors, or 283 horse power, for grinders and polishers; 62 motors, aggregating 197 horse power, are used in paper works; 57 motors, or 192 horse power, for sausage machines; 21 motors, or 20 horse power, are used by color manufacturers; and 18 motors, or 25 horse power, drive sewing machines. In addition to these are 29 washing machines, 13 ironing machines, 11 leatherworking machines, and 13 machines for electrotyping purposes, aggregating 43 horse power; 3 motors, or 63 horse power, for driving dynamos, and 205 motors for various purposes, requiring together 636 horse power.

SELECTED FORMULÆ.

Bug Exterminators.—Below follow a few formulas for bed bug exterminators, as recommended in various quarters:

Benzin Compound.—

Colocynth	5 g.
Insect powder	5 "
Benzin	100 "

Buchheister's Bed Bug Exterminator.—

Tobacco	100 g.
Insect powder	100 "
Carbolic acid	75 "
Boric acid	25 "
Oil citronella	4 "

Borosalicylic Solution.—

Sodium borosalicylate	20 g.
Water or quassia decoction (5:100)	100 "
Spirit lavender	50 "

Picric Acid Mixture.—

Picric acid	5 g.
Stearic acid	10 "
Paraffin	10 "
Oil clove	5 "
Kerosene	250 "

Hager's Bed Bug (Paste) Powder.—

Persian insect powder	100 g.
Pellitory	100 "
Carbolic acid	5 "
Oil citronella	5 "
Dilute alcohol	enough.

Make a thin paste, which is to be brushed into the cracks.

A heroic remedy is the following, recommended some time ago in the SCIENTIFIC AMERICAN, viz.:

Arsenic	2 ounces.
Corrosive sublimate	¼ "
Venetian red	¼ "
Lard	13 "

The next is also from the same source, but is indorsed no more than the preceding:

Corrosive sublimate	1 ounce.
Muriatic acid	2 "
Water	4 "
Decoction of tobacco	16 "
Oil of turpentine	16 "

Liquid bug exterminators are usually applied with a brush, but a much better method is to employ a machinist's oil can, a fair substitute for which is a bottle in the perforated cork of which is inserted a quill.

A few words about the bed bug itself may not be inopportune. The cimex, or more properly acanthia lectularia belongs to the division of insects known as hemiptera (half winged), subdivision heteroptera (dissimilar-winged), although few people suspect that they are first cousins to the equally vengeful mosquito. Heteroptera are characterized by two dissimilar pairs of wings, but in the house bug these wings are wanting or extremely abortive. Blood is not their sole nourishment, but in case of necessity they content themselves with various vegetable juices; however, they can live a very long time without food, when they become almost transparent. The female is supposed to deposit its eggs—about 50 at a time—in the alternate months of March, May, July and September, the young brood requiring eleven weeks to mature. The vigorous individuals of the September series live through the winter, the greatest cold being unable to kill them.

Aristoteles taught that house bugs are generated in the perspiration, but they are supposed to have been introduced from India. In the latter country they must surely be luxuriating, since in hospitals a bug trap is a necessity, this trap being a board full of minute bore holes which is placed beneath the mattress, whence it is removed from time to time to be scalded.—Western Druggist.

Plating Aluminum.—To plate aluminum with gold, silver or nickel, by the galvanic process, it is necessary to first coat the article with a covering of copper. This is best done as follows: First wash the metal thoroughly in a solution of soda, then carefully remove all the soda by immersing the article in running water; next place it in hot hydrochloric acid, diluted to contain 5 per cent. of acid. Wash again and put into copper sulphate solution, slightly acidulated. When a thin cover of metallic copper has formed, the aluminum is ready for galvano plating—but must first be washed.—Wiener Gewerbe Zeitung.

Liquid Starch Gloss.—

Distilled water, fluid measure	100 parts.
Borax, by weight	10 "
Gum arabic, by weight	10 "
Spermaceti wax, by weight	10 "
Glycerine, by weight	27 "

½ per cent. oil of lavender.

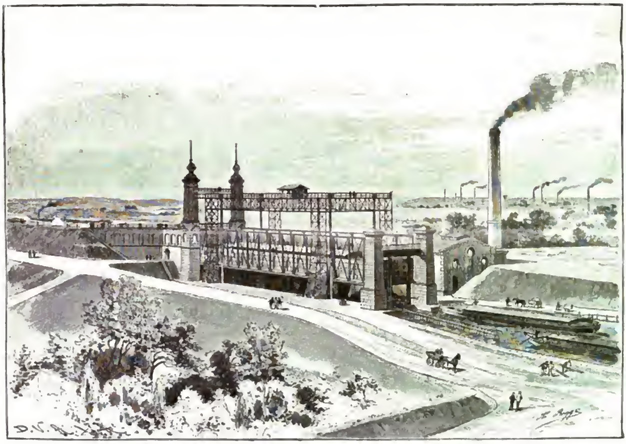
Dissolve the borax in water, and then dissolve the gum in this solution, and gently warm it sufficiently to dissolve the wax. Then put the whole into a warm stoneware mortar, and rub up the whole until the wax has emulsified, i. e., formed a creamlike emulsion, with the fluid. Then gradually add the essential oil, and finally stir in the glycerine, being careful to stir all the while it is being added, so as not to cause the separation of the components. Some little skill is required in forming an emulsion, for, if not properly done, the ingredients will separate on standing or on the addition of water. In a properly formed emulsion no such separation will occur. One secret of success consists in stirring the mixture always in one direction, say from left to right. Never reverse the stirring process, or you will assuredly cause separation of the constituents. Another secret is to maintain the temperature constant until the last morsel of wax has entered into combination—it is only a physical, not a chemical one—with the other ingredients. In the last formula the glycerine may be dispensed with if desired. The directions for use are to be: One teaspoonful of the liquid gloss added to each pint of boiling hot starch made in the usual way, and the fabric starched in the usual way. Or the linen may be first starched in the usual way with plain starch, and then a rag dipped in the gloss, squeezed out, and lightly smeared over the starched portion, and the ironing proceeded with as usual.—Pharmaceutical Era.

THE DORTMUND-EMS CANAL.

OF all Germany, Westphalia is one of the most favored provinces. In the east and north fertile fields and rich orchards extend far and wide over the land, liberally yielding their treasure, while in the mountains that rise from the banks of the Sieg and Ruhr lie hidden coal and iron, the foundations of industrial prosperity. The valley of the Sau, on the other hand, the Switzerland of Westphalia, delights the traveler with its vast oak forests and pine woods. Nature has greatly blessed the country, but one thing it has been denied: no great river pours its crystal wave through the land, opening a path whereon the merchant vessel may carry the riches of the land away over buoyant waters to the northern market. But where the hand of Nature has not provided, man's skill must be called to aid. For years it had been purposed to build a canal to connect the industrial center of Westphalia with the North Sea. Only lately this plan came into execution, some forty years after its promulgation, forty years which must have caused a large pecuniary loss to the German province. At the present time the great canal is completed, and henceforth, no doubt, Westphalian industry will flourish more than ever.

A silver streak, the Dortmund-Ems canal, extends from east to west through green meadows and dark forests, here and there with a pretty cottage reflecting in its waters. The mountainous nature of the soil has in many places called the engineer to work. Numerous bridges and viaducts cross the canal.

The Lippe bridge at Oelfen, in particular, is a masterpiece of engineering. It is nearly 49 feet broad and 227½ feet long. Many obstacles had to be removed, many structures to be erected to render the plan of a canal practicable. The most imposing and the greatest of such is the one we give an illustration of. At Heinrichenburg the level of the canal changes by some 45 feet, and the transferring of the barges from one portion to the other is contrived by an ingenious elevator system. It will give our readers some idea of the vastness of the machinery if we mention that the length of the moving reservoir for the barges is 245 feet. Our illustration shows it lifting a barge, the work being just half completed. Under the reservoir there are five floats, which are firmly attached to the reservoir by steel beams, and which are wholly immersed in water. The upthrust of the floats is exactly equal to the pressure due to the weight of the reservoir, etc., so that a small force is able to lift reservoir and barge to the higher level. This giant structure is remarkable as the greatest and, technically, most perfect of all similar mechanisms in the world. Our illustration is taken from Ueber Land und Meer.



THE SHIP ELEVATOR AT HEINRICHENBURG, ON THE DORTMUND-EMS CANAL.

THE UTILIZATION OF ALUMINUM IN THE ARTS.

UNDER the above title Alfred E. Hunt, president of the Pittsburg Reduction Company, delivered before the Franklin Institute, Philadelphia, a lecture from which the following excerpts are taken.

Until within ten years it was believed that if any one should be fortunate enough to produce aluminum so as to retail it at $1 a pound, the consumption of the metal would be enormous; and that if it could be sold at fifty cents a pound, the demand for the metal would be prodigious.

Early in the progress of the Pittsburg Reduction Company my attention was called by the necessities of the case to the fact that the problems connected with the sale of aluminum, its adaptability for various purposes and the progress of the utilization of the metal, were as intricate as the problem of the cheaper production, and required as much research, offering a great many more opportunities for remuneration than would the search for cheaper methods of production. The perfecting of details in the higher processes as carried on at Niagara Falls, Pittsburg and Kensington have already allowed the aluminum to be sold at 31 and 32 cents per pound in ingots, while the relative price in sheets over ingots is not greater than that charged for copper and brass. Copper sheet has a specific gravity of 8·93; brass sheet, 8·15 to 8·20; aluminum sheet runs 2·62 to 2·66; so that copper is $3\frac{4}{10}$ times and brass $3\frac{14}{100}$ times heavier than aluminum.

The output of aluminum in the United States in 1896 was about 1,300,000 pounds, and the output for 1897 will be about 2,000 tons; and I estimate a consumption of only about 1,000 net tons in the United States.

The uses of aluminum have enlarged very much in the past eight years; and from a consumption of not over 100 pounds per annum and selling at not less than $8 a pound, it has increased to 100 tons in 1896.

One of the most important uses of aluminum has been its utilization in the manufacture of steel ingots and steel castings. Many attempts have been made to alloy aluminum with iron and steel; but no very satisfactory results have been so far obtained. The influence of aluminum seems to be as a softener rather than a hardener of iron. Aluminum combines with iron in all proportions; but an alloy of 50 per cent. aluminum and 50 per cent. of iron, while casting into a solid mass, will crumble into powder in a very short time. Aluminum is largely used in the manufacture of steel; but the amount is very small and varies with the steel being made, the amount of occluded gases and the temperature of the molten metal. It is put into the ingot mould, or groups of moulds, until the proper proportion has been determined, starting with two ounces to the ton of steel and increasing to four or five ounces to the ton, according to the result desired. Bessemer steel requires one to three ounces more per ton than open hearth metal to produce the same effect. The special advantages to be gained by the use of aluminum in steel manufacture are as follows: First, increasing the soundness of the tops of the ingots, with consequent decrease of scrap (saving loss); second, quieting the ebullition in molten steel, thereby allowing the successful pouring earlier than otherwise; third, adding to the homogeneity of the steel by preventing oxygenation, also by decreasing the time the steel will remain fluid after being poured into the moulds, preventing the central core from hardening longer than the outside portions of the metal. It increases the tensile strength of the metal without decreasing the ductility.

Good steel has been made, using aluminum entirely, instead of manganese. The use of aluminum insures smooth surfaces in castings and ingots. Its use increases the soundness of the fibers of steel ingots and decreases the scrap and other loss. This use of aluminum in the manufacture of steel is adopted almost universally with the principal steel manufacturers, not only in this country but in Europe. The phenomenon of quieting ebullition is a very important one. Steel would ordinarily boil from ten to fifteen minutes before freezing over; and when freezing would rise from eight to ten inches, if ordinary steel, unless something heavy were placed on the top of the ingots. When aluminum is added, the steel will freeze over within thirty to forty-five seconds. There is danger of adding too large a quantity, in which case the metal would form too solidly and create deep pipes in the ingots; the shrinkage due to contraction producing pipes occasioning a serious amount of crop ends. No difficulty has been experienced with mixing aluminum with steel, as it seems to thoroughly permeate the metal without any special stirring.

Prof. Arnold has shown that the blow-holes in steel are primarily caused by carbonic oxide in the metal. Aluminum is the principal deoxidizer known to metallurgists, the next being silicon. One hundred parts by weight of oxygen will combine with fourteen parts of aluminum or 350 parts of manganese. This does not correctly express the deoxidizing power of aluminum; as it has such a great affinity for oxygen that the latter will entirely disappear where aluminum is present. There is also an additional inducement to use aluminum; for the silicon will add about $1 to the cost per ton of steel, while aluminum will not add over 10 cents to the cost per ton.

Some manufacturers use ferro-aluminum, this being a trade name given to 5, 10, 20 per cent. alloy with iron. Most users of ferro-aluminum make their own ferro by adding known weights of aluminum to known weights of steel cast in convenient moulds. In cast iron, one to two pounds of the metal is put into the iron as it is being poured from the cupola into the melting furnace. Where there are difficult castings to be made, or where the iron will not flow well, aluminum certainly, in many cases, has allowed of better work being done and stronger and sounder castings being made. The effect of aluminum in wrought iron is not very marked. It seems to add somewhat to the strength of the iron, but the amount is not sufficient to induce the general use of aluminum for this purpose.

Aluminum, either pure or alloyed, is sold upon the market by the dealers now in the form of ingots, bars, plates, sheets, rod, wire, tubing and castings. Among the alloys, there are several kinds of purposes for which it is to be employed. The principal hardeners are copper, nickel, zinc, manganese, titanium, tungsten and vanadium. It has been found practicable to combine several of these metals in the different forms, rather than using them singly to form alloys.

The ordinary commercial aluminum contains over 99 per cent. of pure aluminum. Casting aluminum can be very much improved in rigidity and tensile strength if afterward subjected to drop forging processes. One of the particular uses of aluminum at the present time is in the fabrication of aluminum cooking utensils, for which it is well adapted by reason of its lightness, resistance to corrosion, ease of keeping clean, and high specific heat. It is made up in the form of cast hollow ware and stamped or spun.

In shaping aluminum wares better work can be obtained by the stamping process. The spinning operation being of such a character as to spread apart the metal, a much more open surface for corrosion is exhibited than when stamped.

One of the great advantages of aluminum is that the salts occasioned by its corrosion are not in any way

poisonous. It may be kept clean from corrosion by the same care bestowed on brass or other bright work.

Pure aluminum is not as readily corroded as the alloys of the metal. With imperfectly made aluminum there is sometimes metallic sodium alloyed with it. Its presence occasions rapid corrosion, that is, corrosion of the sodium in the aluminum leaving the aluminum of such porous character that it corrodes much more rapidly.

Aluminum is receiving extended use in chemical laboratories, in water baths, Bunsen burners, hot water filters, and condenser tubes.

(To be continued.)

ELECTRIC PLOWING.

OUR grandfathers plowed with oxen and horses, and at that remote epoch in which the railway and the telegraph had not as yet perturbed the existence of farmers they derived much benefit from this slow but sure process of labor, the traditional character of which flattered their conservative instinct. But, with the progress of the transportation industry, competition made its appearance, and it became necessary to recognize the fact that animal power was not everywhere and always the most economical and rational as regards plowing. So the larger cultivators have had no hesitancy for the last thirty years in having recourse to the various systems of steam plows, the many advantages of which have long been universally known. We say large cultivators, because, while recognizing the excellence of the mechanical process brought into play by his rich neighbor, the plowman of small or moderate means hesitated about spending the amount of money necessary to purchase steam plowing apparatus and to keep it in repair. At present, therefore, although the steam plow is in common use in farming on a large scale, it is almost entirely excluded from exploitations whose importance is not of the first order.

But where steam has not been able to succeed completely, electricity might well prove an economical solution of the problem of plowing. The first trials of the application of electricity in this direction are due to M. Felix, of Sermaize, who a few years ago conceived the idea of substituting a dynamo for a locomotive steam engine for plowing purposes. In this system the expenses were too high, and it is only quite recently that the Messrs. Zimmermann, of Halle, have devised an arrangement that permits of a much more economical use of electric power. They produce electricity by means of a locomotive apparatus that may be placed upon a road or at any point whatever of a field, and carry the energy through cables to a receiving dynamo that forms part of the plow and produces the displacement of the latter. Let us say at once that in farming on a large scale in which steam engines of high power are used, and in sugar works, distilleries and other agricultural works dependent upon the direct exploitation of the soil, it is advantageous to make use of these for actuating the dynamo. Setting aside these large installations in which there exist powerful stationary engines, and also those in which are found waterfalls capable of yielding the necessary power in the vicinity of the fields to be plowed, we are going to see in what consists the arrangement normally necessary for electric plowing. As we have already said, if the generating source of the current changes, it is merely necessary to modify the wiring that conducts the energy, and the principle of the method is not altered.

An endeavor has been made, in the first place, to make the apparatus light, so that the farm animals can haul them without difficulty to the points where they are to be employed, and to permit of the use of the agricultural locomotives that are employed for other purposes, so that the capital invested shall not be increased. The following is the arrangement that has been decided upon:

The plow is of the tilting type, and carries a dynamo. Upon the shaft of the latter there is mounted a double gearing that transmits motion to a second shaft, upon which is keyed a wheel, which guides a chain that is stretched over the field to be plowed and is anchored at its two extremities. When the motor is thrown into gear it draws upon the chain and causes the plow to move forward. At the end of the course the plow is tilted and the direction of the current reversed, and the plow returns to the other extremity in unwinding the chain. The anchors that fix the two extremities of the latter are maneuvered by means of a simple lever upon which the action of one man suffices to pull them up.

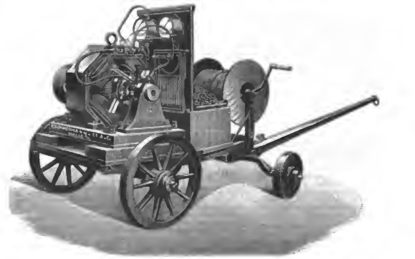


FIG. 1.—A GENERATING DYNAMO MOUNTED UPON A CARRIAGE FOR ELECTRIC PLOWING.

In small and medium cultures, any 12 or 15 horse power locomotive may be used. The generating dynamo is placed upon a wagon which, in the displacements, is coupled to the locomotive. When a person reaches the place where he wishes to install his source of energy, it suffices to connect the flywheels of the motor and dynamo by a belt. The only condition that the locomotive has to fulfill is that of having a very sensitive regulator, as, in fact, is required in every engine that actuates a dynamo.

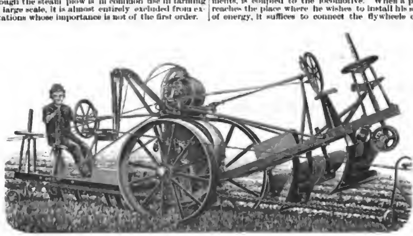

FIG. 2.—THE ELECTRIC PLOW OPERATING IN A FIELD.

The transmission of the electric energy is effected by means of wires corresponding to the two poles of the dynamo and supported by poles through the intermedium of insulators, just exactly as in a telegraph line. The poles are placed along the edge of the field at right angles with the direction that the plow is to follow. In order to take the current from these wires, two trolleys are employed, and these are connected with wires parallel with the travel of the plow. These wires at the two ends are wound around tension carriages and supported here and there by small carriages that participate in the shiftings of the plow. The wires, supported and stretched, as has just been seen, rest upon two special contacts carried by an arm that forms part of the plow. They thus transmit the current to the receiving dynamo through the resistance box. It is this same arm carrying the contacts that lifts the carriages and arranges them at the desired distance apart to effect the return of the plow. The plow is provided with two shares, each preceded by a small colter. It may be completed by scarifiers that stir up the earth to a depth of sixteen inches without turning it over, while the shares plow to a depth of about ten inches. The plow moves forward at the rate of 230 feet a minute.

The installation of the material requires half a day's work; but the time thus employed is soon compensated for by the acceleration obtained in the operation of plowing. Experiments made in Germany have shown that it is possible to plow more than four acres to a depth of ten inches in ten hours. To do the same work in the same time by the old method, it would require four teams of six oxen. The latter walk at a speed of scarcely more than fifty feet a minute.

For heavy soil it would be necessary to construct plows of a somewhat different style, but the installation would be practically the same. The power necessary varies according to the nature of the soil.

In farming on a large scale, in which it is necessary to plow to a greater depth (to fourteen instead of ten inches), and in which it is also necessary to plow from eight to twelve acres per day of ten hours, the installations include, as a general thing, stationary engines and a transmission of energy through coarse wires of polished copper, like those of telegraph lines. The rest is arranged as above stated, with the exception of a few details.

It is estimated that the expense of electric plowing is only about half of that of steam. This is a fine result, and we think that M. Maguin, who is constructing the Zimmermann material in France, will find numerous customers.—La Vie Scientifique.

ADVICE TO BUILDERS OF ELECTRIC RAILWAYS.

By G. WHITEFIELD CHANCE.

As president, manager or superintendent of a railway system, you are interested in motors, brakes, coal bills, salaries of employes, and most of all, earnings. You try to figure down your operating expenses, but, perhaps, like the famous ghost, they will not down. You are looking for leaks. Can you see prospective dividends vanishing before inevitable repairs and renewals?

What do you think of a large city system of electric roads with a nine inch girder rail, under a traffic of 450 car trips per day, after three years' service, crying through motors, cars and riders, for reconstruction. And yet this is only one case out of scores where material was all right but handling all wrong. You are an able financier and manager, but perhaps are handicapped by the lack of foresight of someone.

Roadbed.—In interurban railroad building along country roads, the question of drainage is most important; so also in cities this is an important question, except with good foundation and practically watertight pavement, or where the track is laid on concrete. Often a cheap line of drain tile is as effective as a foot of stone ballast. Especially on comparatively light traffic roads designed to be built cheaply will correct drainage treatment show marked saving. Experience on steam roads has taught us that we dare not obstruct nature, and yet how often is precedent thrown aside? To fully appreciate the value of drain tile one must have lived in or visited "the drain tile States."

Concreting.—There is more money thrown away in bad foundation work than is generally realized. But this special part of your track work is frequently a case of "the devil take the hindermost." If you are laying rails in cities, where excavation is required, no more material should be taken out than is absolutely necessary to get in the foundations. Some work is very loosely done in this respect; a solid bottom should be insisted on in any case. If you are laying where the roadbed can be rolled, it should be done by all means. If heavy traffic is the word, concrete first, last and all the time, and perhaps you may do away with ties entirely, if the conditions are favorable.

Ties.—There are two standard ties in this country, white oak and yellow pine. I have learned, as we all have who have had much to do with the question, that there are ties and ties, and that a competent inspector will save a small fortune to a large company. How many roads in building or even in renewals get what their specifications call for? While there are two standard woods, others may be used in certain localities by using good judgment as to traffic and local conditions, and then comes in the question of the tie plate, its advisability and form, questions again of suiting your appliances to your conditions. A cypress or cedar tie with a tie plate, in certain localities, may be much better and more expedient than a harder wood. A tie plate, even with hardwood ties, is a great saver with heavy traffic or tortuous alignment. Yet again, it may be unnecessary with easy alignment and light traffic. Timber treatment, creosoting and kyanizing are well known methods of increasing the life of the tie and may be used with judgment in certain cases.

Rails.—There has been much written about rails, chemical composition, length, form, etc. For nearly all purposes of track construction, the long rail, preferably the 60 foot rail, has come to stay. The broad, shallow head, high web and moderately wide base give the best results. Where tie plates are to be used, we would naturally use a moderately wide base, but the market forms will have to govern the selection in most cases. The American Society rail or T rail work is good and practical. All the high girders by the principal American mills are good in practice, but the foreign girders are generally of bad head design. Perhaps a rail with greater base width than common would give better results when laid directly on concrete. The chemical composition, heat treatment, and mill inspection are points too little looked after in giving rail contracts. High carbon, low phosphorus and sulphur with a proper heat treatment is the "battle cry" for good rails. It is entirely reasonable to allow a harder, even if more brittle, rail in sheet girder work than in steam work, where a broken rail may mean loss of life and property.

Joints.—These should be good, or none at all; that is, your rail can be practically continuous if you bury

it in rigid paving. We are not yet to the point of laying continuous rail in open track, although recent experiments with cast joint continuous rail seem to point that way. By laying so as to make the stress generally one of tension, with perhaps a slight compressive one at times, and using proper anchorages at curves, we may attain to a continuous rail in open track. But when you must have a joint, let it be the best. If you are using a low rail, use a heavier joint plate in proportion than with a high rail. I would much prefer a joint plate of the type that drops below the base for a T rail, or a combined tie and joint plate. The mistake is nearly general in using a small joint plate with a small rail, with the consequence of a bad track, surface bent rails and general inefficiency. The poor fish splice used with light rails has done more to condemn the rail than the rail itself. My own experience and that of many experts has demonstrated the fact that light rails wear proportionately better than those of heavier section. This is explained by the fact that the head of a light rail gets more work done on it by the rolls and is of a denser construction. In the matter of continuous rails the cast joint is cheaper than the electric weld, by something less than half, a nine inch cast weld joint costing about $3.50, while an electric weld of the same rail costs about $5 per joint.

Bonding.—Whatever style it be, copper, plastic alloy, electric or brazing weld, let it be well done, to which end thorough inspection is necessary, for as with all track work, we usually say good-bye to this part of the system when the "fliers-in" come along. With the cast joint there is a difference of opinion as to the necessity for bonding, some bonding their joints and others maintaining this unnecessary. However, if the right means are at hand, the cast joint can probably be made electrically sound.

Special Work.—Having been engaged in the manufacture of special work for some time, I may here add a word or two of interest and value. We have frogs and crossings now with hard centers—manganese, Harveyized and case-hardened. They are all good and fastened about the same in the first two cases. We have also solid cast steel pieces which are well made. While certain pieces of one manufacture will outwear those of another manufacture in a certain locality, the difference on the average is slight, and great difference of wear can generally be traced to non-uniformity of product. On this account, a guarantee from the maker is in order. The trouble with this class of work is that it is more or less going through the experimental stage. Where you have curves of very sharp radius with heavy traffic, a special steel should be considered. Manganese is the best yet found. Your curves should of course have easements, and the outer rail should be elevated if possible. All curve rails, whether T or girder, of less than 500 feet radius, should be bent at the mill, and if of heavy section, up to 750 feet radius. Switches and mates are also made with special steels in tongues and central wearing parts. These are the best, but for light traffic the less expensive styles will do; however, all depends on how light the traffic is.

Bridges and Culverts.—The number of bridge accidents on suburban trolley lines has been too great. Don't take any risk; you cannot afford to, even if you are operating a cheap line, for if you lose a bridge and a few lives culpably, where will dividends for years go to? Better err on the side of safety, if you must err, but with competent supervision and careful inspection there should be no erring and indeed no unreasonable expense. A guarantee or insurance may relieve you of pecuniary responsibility, but for the good name of your road you cannot afford to have accidents. "Sufficiency" is the word. Don't try to make water run up hill. Give it room.

Overhead Line Work and Conduits.—Your pole line, frogs, conduits, etc., should be good construction and standard practice. There are so many electrical nostrums in the way of overhead fixtures that it takes some care to select the best for the money expended. Poles should be set in concrete. Compressed mica insulators are the best. Creosoted wooden ducts for cables are standard. When the third rail system can be used, it is best and cheapest.

Motive Power.—You may be pleased and edified to note the progress made in compressed air, gas, steam, and other motors, but experience teaches, and it has not yet demonstrated these motors to be superior for urban and ordinary suburban service. The accumulator car, and compressed air motors, are worthy of study, and in certain situations these motive powers may yet find a field.

Power Stations.—The subject of location is both a mathematical and ordinary financial one, and should be left largely to the engineer. For a first-class plant of large units compound condensing engines, water tube boilers, automatic stokers, economizers and direct connected generators are the essentials of economical operation. For a small plant, high speed automatic engines, with belted generators, give good results, while the automatic stoker and economizer may be dispensed with. The subject of pure water supply, purifiers, heaters, pumps, separators and condensers are details that must be worked out in each case.

Cars.—For urban service the single truck car is best, for fast interurban service the double truck car has many advantages. The simpler the truck the better, provided the principle is all right. For fast service something more than the hand brake should be used. The air brake and electric disk brake are both available. The latter has been brought to a state of perfection that will probably meet all requirements, and it possesses the advantage of a direct method of application of power.

Operation.—There is entirely too much looseness in methods of operation of electric interurban roads. For single track lines, either a dispatcher system with orders should be used or an electric train staff system or automatic block. With double track lines an automatic electric block system will meet all requirements.—Western Electrician.

Steiger (Corres. Bl. f. Schw. Aerzte, May 15, 1897) found that of about twenty thousand eyes of children in the primary classes in the schools of Zurich, 1570 were more or less defective. About one-half of these, or 777, were astigmatic. In some of these the affection was light, but in 662 it was described as considerable, while in 318 it was marked.

NUTRITIVE VALUE OF FOOD.

In order to ascertain the customs and methods of persons of different stations in life regarding the purchase and use of their food, a series of investigations are being conducted by the Department of Agriculture. These inquiries are of a distinctly practical character, and they are made with the co-operation of a number of experiment stations, colleges, and other organizations, as well as of private individuals, in different parts of the country. The general scope of the investigations includes the determination of the amounts and nutritive value of the food consumed by a given number of persons during a certain number of days, and the deducting of the quantities per man per day.

It is believed that such information, coupled with that derived from the study of the composition, digestibility, and nutritive value of food materials in common use on the one hand, and with that which comes from research into the laws of nutrition on the other hand, will gradually make it possible to judge what are the more common dietary errors and how improvements may be made to the advantage of health, purse and home life. A variety of digestion experiments have already been made, and others are in progress under governmental supervision. Accounts of studies of dietaries of families, boarding houses and clubs are from time to time made the subject of official reports.

HOW EXPERIMENTS ARE MADE.

In these studies account is taken of the amounts, composition, and cost of all food materials of nutritive value in the house at the beginning, purchased during and remaining at the end of each experiment, and of all the kitchen and table wastes. Such accessories as baking powder, essences, salt, condiments, tea, coffee, etc., although of interest from a pecuniary standpoint, are of no practical value as regards nutriment. The sum of the different food materials on hand at the beginning and those received during the experiment is taken, and from this sum the quantities remaining at the end are subtracted, thus giving the amount of each material actually used. From the amount thus obtained and the composition of each material, as shown by analysis, the amounts of the nutritive ingredients are estimated. From these are subtracted the amounts of nutrients in the waste, and thus the amounts of nutrients actually eaten are learned. In all of these experimental inquiries account is kept of the meals taken by the different members of the family and by visitors. The number of meals for one man, to which the total number of actual meals taken is equivalent, is estimated upon the basis of the potential energy. These energy equivalents are somewhat arbitrary, and it is acknowledged that they will require revision in the light of accumulating information.

Following is a table of estimated relative quantities of potential energy in nutrients required by persons of different classes:

Man at moderate work	1·0
Woman at moderate work	0·8
Boy between 14 and 16, inclusive	0·8
Girl between 14 and 16, inclusive	0·7
Child between 10 and 13, inclusive	0·6
Child between 6 and 9, inclusive	0·5
Child between 2 and 5, inclusive	0·4
Child under 2	0·3

WHERE STUDIES HAVE BEEN MADE.

The dietary studies already made include a boarding house, a blacksmith's family, a jeweler's family, a chemist's family, an infant nine months old, a college students' eating club, a Swedish laborer's family, a female college students' club, farmer's family, a camping party in Maine, a poor widow's family, a man in the Adirondacks under treatment for consumption, and a mason's family.

As a general thing, the figures used for the percentages of nutrients in each food material are taken from the averages given for like food materials in Bulletin No. 28 of the Office of Experiment Stations of the Department of Agriculture.

The figures in that bulletin represent the results of a compilation of analyses made previous to January 1, 1895. In estimating the fuel values of the nutritive ingredients, the proteine and carbohydrates are assumed to contain 4·1 and the fats 9·3 calories of potential energy per gramme. These correspond to 1,860 calories for one pound of proteine, or carbohydrates, and 4,220 calories for one pound of fats.

FUEL VALUES OF BACON, TURKEY AND COD.

Bacon has a very large percentage of fuel value. The latest official analysis shows that a portion of bacon, with the inedible parts discarded, contains 17·8 parts water, 9·8 parts proteine, 68 parts fat, and 4·4 parts ash, and has a fuel value of 3,030 calories per pound. By the same analysis, the edible portion of a turkey is found to contain 55·5 parts water, 26 parts proteine, 22·9 parts fat, and 1 part ash, with a fuel value of 1,350 calories per pound. Codfish, edible portion, contains 82·6 parts water, 15·8 parts proteine, 0·4 part fat, and 1·2 parts ash, and has a fuel value of 310 calories per pound.

In each of the dietary studies reported the data regarding the kinds and amounts of food material, the persons by whom they were eaten, and the number of days and meals were sent to the Government Experiment Station at Middletown, Conn., where the necessary computations were made. For the sake of simplicity and convenience, the computed quantities for one man for ten days are given, instead of the actual quantities consumed, or the quantities for one man for one day. If the quantities were stated as actually consumed in the period of each dietary, it would not be easy to compare the quantities in different dietaries. By putting the quantities for all of the dietaries on one basis, however, the relative amounts of the different kinds of food materials, as meats, milk, bread and the like, in the different dietaries are readily compared. If the quantities were given per man per day, some would be too small for printing without the use of an inconvenient number of decimal places.

WHAT A LABORER'S FAMILY ATE.

A fourteen days' study was given to the dietary of a laborer's family in Hartford, Conn. The family consisted of man and wife, three girls, aged respectively four, six, and eleven years; a boy, two and a half years old, and an infant. The father was a laborer in a coal yard, earning $8 per week. The mother had worked as a servant before her marriage and did her own cooking. The food materials bought by this family consisted of beef, veal, mutton, pork, salt codfish, eggs, butter, milk, rice, flour, rolled oats, bread, beans, sugar, potatoes, onions and raisins. The consumption of food, calculated for one man ten days, was: 13·2 pounds of animal food, 9·6 pounds of cereals and sugars, 11·1 pounds of vegetables, and 2 pounds of fruit—a total of 34·1 pounds. This total quantity cost $1.63, and it contained 2·41 pounds of proteine, 2·24 pounds of fat, and 9·59 pounds of carbohydrates, the aggregate fuel value being 31,700 calories per pound. The following table shows the nutrients and potential energy in the food purchased, rejected, and eaten by this entire family during the period of fourteen days:

FOR FAMILY, 14 DAYS—FOOD PURCHASED.

Food materials.	Cost.	Nutrients. Proteine. Grms.	Fat. Grms.	Carbohydrates. Grms.	Fuel Value. Calories.
Animal	$5 62	3,312	5,239	1,076	66,710
Vegetable	3 51	2,816	444	23,519	112,100
Total	$9 13	6,128	5,683	24,595	178,810
* Total	..	38	99	98	1,480
† Total	9 13	6,090	5,584	24,497	177,330

* Waste.
† Food actually eaten.

PER MAN PER DAY—FOOD PURCHASED.

	Cost.	Proteine.	Fat.	Carbohydrates.	Fuel Value.
Animal	$0 10	59	94	15	1,175
Vegetable	0 06	50	8	420	2,000
Total	0 16	109	102	435	3,175
* Total	..	1	2	2	30
† Total	0 16	108	100	433	3,165

* Waste.
† Food actually eaten.

WHAT A CAMPING PARTY REQUIRED.

In the summer of 1895, four young men, from nineteen to twenty-two years of age, spent some time in canoeing and camping on the Allagash River, in Maine. As they took their journey leisurely, they may be considered as being engaged in light work. The whole time included in the dietary study of this party is estimated as equivalent to 115 days for one man. The following table shows the nutrients and potential energy in the food purchased, rejected and eaten by this camping party:

FOOD MATERIALS.

Food materials for party.	Nutrients. Proteine. Grms.	Fat. Grms.	Carbohydrates. Grms.	Fuel Value. Calories.
Food purchased:				
Animal	12,169	27,396	2,331	314,230
Vegetable	7,616	2,625	59,018	297,610
Total	19,785	30,021	61,349	611,840

PER MAN PER DAY.

	Proteine.	Fat.	Carbohydrates.	Fuel Value.
Food purchased:				
Animal	106	238	20	2,730
Vegetable	66	23	513	2,590
Total	172	261	533	5,320

The average of thirty-eight dietaries recorded by the government officials makes the following interesting showing:

DIETARIES.

Dietaries.	Nutrients. Proteine. Grms.	Fat. Grms.	Carbohydrates. Grms.	Fuel Value. Calories.
Food purchased	111	140	447	3,595
Food waste	7	11	13	185
Food eaten	104	129	434	3,410
Estimated digestible nutrients in food eaten	96	124	423	3,285

CHARACTER OF SANDOW'S FOOD.

About a year ago, during an engagement of Eugene Sandow, the "strong man," in Washington, an attempt was made to determine the character and amount of the food he consumed. Mr. Sandow claims to be the strongest man in the world, and at the time of the investigation he had the appearance of being in perfect health. He did not then follow any prescribed diet, but ate whatever he desired, always being careful, as is his custom, to eat less than he craved. He always ate very slowly. He smoked a great deal, and drank beer and other beverages. Below is the result of a study of Sandow's dietary for one day:

Food consumed (Quantities in ounces.)	Nutrients. Proteine.	Fat.	Carbohydrates.	Potential energy.
	Lb.	Lb.	Lb.	Cal.
Dinner January 18. 8 oysters, 10 soup, 1 celery, 3 fish, 1 potatoes, 2 oyster plant, 1 green peas, 1 tomatoes, 2 bread, 2 roast beef, 2½ chicken, 4 ice cream, 3 orange sherbet, ½ cakes, 1 butter, 11 wine (Burgundy)	0 17	0·14	0 34	..
Supper. 8 roast beef, 7¼ rye bread, 3½ Camembert cheese, 3 water biscuit, 3½ cakes, 4·1 lb. beer	0 36	0 14	0 61	..
Breakfast, January 11. 9 vegetable soup, 2 potatoes, 3 veal (deviled chops), ½ green peas, 2 roast beef, 3½ bread pudding, ½ cakes, 14 beer	0 11	0 05	0 16	..
Total in pounds	0 54	0 33	1 11	4462
Total in grammes	244	151	502	..

It was noted that Sandow rejected all of the visible fat of the meat served him, and in his case it was shown that while the amount of carbohydrates and fat consumed did not differ very greatly from the standard

for a man at muscular work, the amount of proteine (albumen) was very large. The fact that so much proteine was consumed by Sandow sustains the theory advanced by scientific experimenters that the energy which is used in the production of severe muscular labor is furnished by the combustion of proteine.

Official experiments regarding the digestibility of food by healthy men are now in progress. It has been demonstrated that 98 per cent. of the proteine and 97 per cent. of the fat in animal foods is readily digested; also that 85 per cent. of the proteine and 90 per cent. of the fat in cereals and sugars, and 80 per cent. of the proteine and 90 per cent. of the fat in vegetables and fruits is readily digested.

DO WE TAKE TOO MUCH ACID FOOD?

THE affirmative of this question is strongly maintained by Dr. W. T. English, Pittsburg, in a paper read on June 3 before the Section on Physiology and Dietetics of the American Medical Association, at its annual meeting in Philadelphia, and published in the Medical News (July 17), from which we quote the following paragraphs. The writer begins by noting that, instead of confining our use of acid fruits and vegetables to the summer months, as Nature intended, we now eat them all the year round. He says:

"It would be impossible within the scope of this paper to refer to the individual products concerned in the ever-increasing list of acid foods consumed in this country. Let a few suffice. Tomatoes, which depend for their flavor upon a peculiar acid (acidum lycopersicum), have rapidly grown in favor, until, from comparative obscurity, they have reached the head of the list. It has been estimated that during the years intervening since 1890 this vegetable has multiplied in production ten times.

"Each week during 1885 it required twenty five carloads of lemons to supply the city of New York. At the present time the daily demand exceeds that amount. This is true of other cities, and for the most part the country demand is proportionately augmented. Oranges are supplied in about the same relatively increased quantity. Limes are the most keenly acid of all fruits. Almost unknown outside the fashionable drinking halls five years ago, to-day they are a commodity. They are imported pickled as well as fresh, and the bottled juice comes to this country in large quantities from the West Indies. Congress has recently placed a special tax upon this fruit, because of its large importation. The grateful acid of the rhubarb leaf, in conjunction with binoxalate of potash, with the malic acid contained in gooseberries, currants, cherries, plums, apples, and pears, adds to the acidulous tide.

"Recently it was learned from a large commission merchant that apples, to be salable in our markets, must be decidedly acid. Sweet apples are employed only in making cider and vinegar. Some varieties of the small sweet fruit have almost disappeared, and their places have been filled by those that are tart enough to please the present acid taste. . . .

"It is claimed that the cheapness of sugar permits the consumption of acid fruits which otherwise would be distasteful. The ingenuity displayed in bringing acid into a condition to make it palatable serves to prove the increasing tenacity of the acid habit. Sweet and neutral vegetables, as beets, cabbage, lettuce, etc., are often rendered acid in order to give to them the much desired sour flavor. Forty thousand tons of cucumbers are raised and eaten within the limits of the United States each year, and this affords an excuse for the employment of about 1,000,000 gallons of vinegar and acid sauces or condiments. The large pickle factories that began with the decade have been reinforced by new establishments and additions that double their capacity for sending out acid products. The demand for piquant sauces has caused a large special industry to arise within the twelve years now ending. Meanwhile the home culinary department has augmented its capacity as to quantity and variety. A considerable amount of salicylic and boracic acids contributes to the preservation of fruits. . . .

"The realm of acid ingesta geometrically expands when we enter the domain of drinks. In the drinking halls the casual observers cannot fail to be impressed with the tendency to indulge in acid beverages that are of recent origin, while those of more or less remote popularity still occupy their position as to quantity consumed. But if the question were asked to-day as to what is the national drink, it would be answered by the fizz of the soda fountain. . . . Foreign countries know little about the American soda fountain, but it increases the acid consumption one hundredfold in this country. The most profitable and largest part of the druggist's trade to-day is that of the product of the soda fountain. Mineral and vegetable sours contribute to the tide of acids which enter the stomach from this source. . . . Small lunches are supplied at some soda counters, consisting of hot tomato and clam bouillons, beef tea, cocoa, chocolate, coffee, tea, ice cream soda, cake, crackers, etc. The most common demand, however, is for the acid-flavored drinks, including mineral and vegetable acids, with water charged with carbonic acid gas. . . .

"All this obtains, too, in spite of the fact that acids are naturally rejected in early childhood, and only rendered tolerable or agreeable by acquired appetite. The increased consumption of acid foods and drinks cannot be accounted for by the increased population, for it is out of all proportion to its growth. Indeed, our population during the last decade has remained almost stationary, while the acid demand is increasing in geometric ratio each year. The consumption of acid foods has increased out of proportion to all other foods, and the amount of acid drinks ingested has doubled every year since 1890.

"This extending and increasing appetite for acid foods and drinks is evidenced by the self-conscious need that many feel for antacids to counteract acidity of the stomach. Wherever sour drinks are sold there are also the antacid, as bicarbonate of soda, magnesia, etc., on hand for the accommodation of those who cannot uninterruptedly continue the acid pace. Again, medical men will admit that the trend of therapeutics is forced, however unconsciously, into the antacid and antifermentative realm. This is not only because of the introduction of sour acids, but is also due to the fact that the acid conditions favor the development of micro-organisms and promote fermentative conditions in the body. These micro-organisms are always more injurious in their effects than the acids that are used as foods and drinks.

"The various modifications of the digestive function incident to the excessive use of acid foods and drinks are already with us, and the acidulous habits of the body mark a stage in civilization. These facts, stated in connection with the estimates above made, should satisfy all that the acid appetite fostered and gratified is contrary to physiologic law. It may further be argued, however, that the acids employed are not only unfavorable to proper digestion, but that they directly and indirectly modify the chemic composition of the blood and bodily fluids."

We have not space to follow Dr. English as he traces the influence of this excess of acid through all the nutritive processes, when, according to his view, it neutralizes the alkalies in the bile and pancreatic juice, thus rendering them of no effect, and similarly destroys the alkalinity of other bodily fluids, including the blood, which to insure immunity against infection should be normally alkaline. We close with his final paragraph, in which he suggests that the effects of an acid diet may be even more far-reaching than this and may include the sphere presided over by the brain. After noting that when the alkalinity of the serum is reduced the red blood corpuscles contract and lose their vitality, he says:

"It must be remembered that the red blood corpuscles are the servants of the respiratory apparatus, and by this interference with their office there must be a reduction of the efficiency of the functions of respiration. The sympathetic nervous system is influenced by hyperacidity, and causes in turn a general functional derangement of the organs, notably the heart. The intellect is temporarily confused, and in some this confusion reaches out into incoherence of thought and action. The moral influence of these perturbed conditions of heart and mind extend to and pervert the imagination, and in extreme cases leave their permanent impress."

SNUFF INEBRIETY.

IT is a well-known fact that a large number of persons use tobacco snuff to excess.

In some sections of the country this addiction is very general, and prominent in the marked degeneration of the victims.

The narcotic effects of tobacco used as snuff seem to cause a profound depression of all the senses, and the body generally. The higher psychical life appears to suffer most, manifest in loss of pride of character and appearance, diminished ambition to excel in any work, disregard of surroundings and opinions of others. Later, delusions of persecution and injury, with suspicion and doubts of anything that is true.

A form of low general dementia follows, terminating in death from melancholy or acute disease.

Recently another form of snuff taking, in which cocaine is the central drug used, has come into prominence. Cocaine is given for some of the distressing catarrhs and nasal troubles which are so painful. Its narcotic action on an inflamed mucous membrane is very marked, and is quickly followed by a certain fascination to continue the drug which is difficult to control. The possibility of not being able to give up the drug never occurs until symptoms of obvious poisoning appear, and then, in many cases, the mind has lost all power of appreciating its real condition. Voluntary efforts are usually confined to changing to some other narcotic used by the mouth. The effects of cocaine by the nose, in most cases, differ but little from its use in other ways. Yet there is a certain mental fascination in the inhalation, as in the use of the needle, which is hard to overcome. The delirium and pleasing relief, with mild excitement which follows, make this form of inebriety most attractive.

The rapid exaltations of the sense of comfort and strength, and sudden disappearance of pain and mental fears and worriment, all make a powerful impress on the mind and nerve centers. This for a long time is far more powerful than the depression and suffering which follows.

There can be no question that this form of inebriety exists to a considerable extent in all our large towns and cities. A very sensational story of a large number of persons in a certain Eastern village affected in this way has some foundation in fact. It appears that a certain druggist pushed the sale of a nostrum containing cocaine used in this way, until the demand was very large. The appearance of the toxic effects of cocaine in several persons resulted in an exposure of the danger of the drug, and its sale practically ended. No doubt similar instances are occurring in individual cases where the drug is not abandoned, and cocaine inebriety or other drug taking follows. As a nasal remedy it is exceedingly dangerous, and should be concealed and guarded by the physician with great care. The use by inhalation is more likely to become an addiction than by the mouth or needle. The treatment is surrounded with great difficulties, and often taxes all the resources of the physician to the utmost.—Quarterly Journal of Inebriety.

GERMANY'S INDUSTRIAL GROWTH.

THE following encomium on Germany's recent industrial awakening, especially as applied to the textile manufactures, appears in Kuhlow's German Trade Review:

In the year 1879 industrial Germany may be said to have emerged from infancy into youth. From that year on factory chimneys began to jostle and crowd mediæval castle towers. The brick walls of modern factories began to shut from view venerable piles of masonry whose ages were reckoned by centuries. From that year fair Saxony, on the east, began to throw off her humdrum quiet and assume a textile leadership, while on the west the beauties of the Rhine were gradually clouded by the smoke from factory chimneys. Then, too, began the transition of agricultural into urban populations. Quiet, lethargic market places, whose peace and repose had long been a proud heritage, began to resound with the clatter and tread of hurrying throngs; the hum of machinery began to be heard where before no sounds had greeted the ear but those which accompany the easy movements of a contented rural people.

Textile industries had been going on there for centuries, but they were not the industries of to-day; they were industries which did not call for the aggregation of humanity at any one spot, because they depended on individual rather than mechanical effort.

During several decades preceding 1879 Germany's textile industries had scarcely progressed. They had been locally important, but stationary. She did not even supply the demand of her own markets. While the English free traders were, perhaps, not quite unselfishly, preaching their theories, England was marching forward rapidly, because she had extensive foreign markets scarcely open to any other country. Germany was eager to emulate success and was easily infected. She tried free trade for eight or nine years, only to find herself more dependent on England than ever. During that period it was common to read signs in the store windows of German cities bearing the legend, "English goods sold here," though, perhaps, not so common as it is to-day in England to meet the phrase, "Made in Germany." It seems almost incredible that a little over twenty five years ago the production of cotton fabrics in France exceeded that of Germany, and that only by the acquisition of Alsace and her 2,000,000 spindles was Germany able to take precedence of France in the tabulated statistics of the manufacture of textiles.

Before Germany had thoroughly experimented with free trade, the United States, under protection, had performed marvels in debt paying and had practically accomplished material prosperity. This was an example for the world to copy. In 1879 the Germans determined to cast aside the free trade theories and try protection, and from that year Germany has been an industrial factor to be reckoned with. From a weak and insignificant square on the chessboard of the world, she has moved to an absolutely commanding position.

But while, without a doubt, protection was the moving cause of this industrial revolution, it was not the only cause. Protection to her industries would alone have accomplished little of what has been done in Germany since 1879. To the thoroughness of her methods quite as much as to protection must the change be attributed. German methods were as thorough between 1870 and 1879 as they were immediately after, yet she did not advance industrially in that time. She did not lose, except in competition with England, but she did not advance in comparison with other countries. From the moment her industries were protected Germany's industrial future was assured. She leaped and bounded forward with giant strides, which at first made men wonder and now make nations marvel and admire.

Having so well prospered under protection, Germany turned her attention to extending her markets, since she was able to hold her own at home. She profited by the lesson taught by the United States—that of reciprocity with other nations whose commodities she could take without injuring her own industries. Local sacrifices, of course, were inevitable, but they were as nothing balanced against the gains to the country's trade as a whole. During the two years or so since the conclusion of her treaty of reciprocity with Russia, Germany's textile industries have increased phenomenally. The trade of Saxony, of Crefeld and Elberfeld, and of Eastern Prussia, are notable examples. The textiles from these localities now find their way all over the land of the Czar, where before they were practically unknown.

Of Germany's commercial and industrial methods too much cannot be said in commendation. They are typical of the German character—thorough, enlightened, and the result of close observation and application. There may be some ports her textiles do not reach, but they do not compare in number with the ports where her manufactures have superseded those of other countries. In every country where German textiles are sold they will be found to be as closely adapted to local requirements as is possible, and to be marketed according to local requirements.

Since 1879—as hundreds of our own, as well as English, consular reports are constantly stating—German merchants have thoroughly familiarized themselves with the needs of all the peoples of the world who were willing to purchase German merchandise. They have not accomplished this by sitting in their mills or offices and studying consular reports.

It is considered an essential part of a German manufacturer's commercial education that he speaks several languages, and that he shall have spent some considerable time in travel or residence abroad, where business is being done or may be done.

German manufacturers establish wholesale dry goods houses in all important foreign markets, and are represented therein by agents who speak the language and are familiar with local methods and requirements. In fact, from the moment a German manufacturer of textiles determines to push his products in any particular foreign market, he does it very much as though the goods were made there and everything connected with the business was domestic instead of imported. This, combined with a rigid honesty, true representations, and the expectation of only a reasonable profit, has been the method under which German textiles have gained a strong hold all over the world, where two decades ago they were, if not unheard of, at least unknown.

In the past twelve or thirteen years Germany's trade with some foreign countries has increased tenfold; with most it has more than doubled. And this despite the fact that throughout the textile industry wages have been steadily increasing. Skilled labor in Germany often commands a higher wage than in England, while the labor as a whole is nearly as well paid as in England, and certainly much better paid than it was under free trade in Germany, when the industry was not even supplying the home market. Wages have increased, and hours of labor have decreased.

The thoroughness of the German method begins at the beginning—with the mechanic and the laborer. Without efficient labor to carry out the designs of those who plan, enterprise would exert itself in vain. In the German textile industries the most skilled labor is in most constant demand.

It has been pointed out by Lord Rosebery to Englishmen, and by several advanced thinkers in the United States to Americans, that one of the causes of Germany's success in industrial warfare is the superiority of her system of technical education. Her technical

schools will be found in and about every industrial center, and wherever they are found it will be admitted that they have so largely increased the efficiency of the workpeople that equal results could not have been obtained without them.

The technical schools are liberally supported by the state, and they provide the means for all who wish to become expert workmen, instruction being given by day and by night.

But the value of the German method lies as much in her commercial as in her industrial thoroughness. The business is an inheritance from father to son, each in turn endeavoring first to maintain and then to improve the legacy. Johann Esche introduced hosiery knitting into Saxony some two hundred years ago, and that business has descended from father to son to the present day without a break. In another instance there have been only four changes in the personnel of a firm in just one hundred years. The sons of manufacturers are thoroughly trained for their future calling before taking any active part in business. In Saxony, to mention only one center, there are only forty commercial schools where the future merchants are prepared for their successful careers at home and abroad. In these commercial academies the instruction is practical and thorough.

Stock companies are comparatively few. The payment of interest on watered stock and inflated capital is an unknown evil in the German textile industries. Most of the factories are owned by families or small corporations. Enormous profits are not expected, management is frugal, and there is less ostentatious display of wealth, and therefore little greed for the means of making it.

A steel bridge, cantilever, 140 feet in span, to connect the Rue Stephenson, in Paris, with the Rue de la Chapelle, will be put in place over the tracks of the Nord Railroad in a single night without using supports or interfering with the trains.

OBJECTS FIVE THOUSAND FIVE HUNDRED YEARS OLD, RECENTLY FOUND AT DESHASHEH, EGYPT, BY PROF. FLINDERS PETRIE.

CANNIBALISM IN ANCIENT EGYPT.

Prof. Flinders Petrie is now exhibiting the result of the explorations he made last winter at a spot called Deshasheh, on the Nile, about fifty miles south of Cairo. He was fortunate enough to come upon a group of tombs which date as far back as the fifth dynasty, about 3500 B. C. In these he found rude coffins with bones in them, but no mummies; an earlier form of burial had been in existence, in which the bodies were cut up, the flesh entirely removed, the bones carefully wrapped up in cloth, and placed in the coffins. The professor comes to the conclusion, based upon statements by Herodotus, Strabo, and other authorities, that the flesh had been cooked and eaten as a sacred rite in connection with the dead. With the Massagetae, when a man reached an old age, it was considered to be a happy and honorable death to be sacrificed and eaten; and it was looked upon as a great misfortune to die before being entitled to this distinc-

tion, for those who died of disease were not treated after this fashion. One of the rude coffins that contained a cut-up body is given among the illustrations. All the objects represented, with the exception of three from El Kab, are from Deshasheh, and they possess a great interest from their extreme antiquity. In one of the tombs a very fine statue was found. It represents a prince and royal priest, named Nenkheftka; a portrait or careful drawing of his head is given, to show what a man was like on the banks of the Nile 5,300 years ago. This statue is good evidence that sculpture was far from being a primitive art at that early date. There is also a group of the same man and his wife, Nefersemu; also the skull of their son, named Nenkheftek. The wooden chisel and mallet, as they would be useless in cutting stone, are supposed to have been employed for excavating the earth in making graves. It may be mentioned that small baskets, like the one shown in the illustration, are still used in India, where women and children carry earth at railway making or other works.—The Illustrated London News.

THE THEATER OF INSECTS.

By John H. Lovell, in Popular Science News.

The first zoological book printed in England was "The Theater of Insects," by Moufet in 1634. The title of the book would suggest that the author, after the manner of old Izaak Walton, was wont to moralize a bit over his studies of natural history. We fancy that he saw, as upon the stage, both tragedy and comedy in the lives and ways of the little known insect world. "The Theater of Insects" differs from all other theaters in that its busy season comes during the summer months. Just as, in the long ago, historical geology tells us that flowers and insects appeared in the world at the same period of time, so now in the early spring the blooming of the first flowers announces the awakening of insect life. If during the last week of the month of May you visit a cold, damp woodland of Northern New England, your attention will at once be arrested by the handsome and conspicuous blossoms of the hobble bush or wayfaring tree. The large flower buds are formed the previous season, pass the winter wholly naked and open in spring with the appearance of the leaves. This shrub may be easily recognized by its straggling habit of growth, its drooping branches, and the broad flat heads, or corymbs, of flowers of two different sizes. The center florets are small, greenish in color, and in autumn produce bright red berries; while the marginal ones, a single row of which surrounds the corymb, are large, white, and sterile. Their size has been increased at the expense of their power of producing seed, and as their use is to attract the attention of insects, they usually open some days in advance of the inner and smaller florets. But for them, the blossom would easily pass unnoticed amid the budding foliage, as may be easily proved by cutting them off. Since their conspicuousness is useless to themselves, but of benefit to the community, they may be said to unconsciously play the part of benefactors.

A sort of barter or exchange is carried on between the flowers of the hobble bush and the insects, by which each is of service to the other. A small quantity of honey, in a thin layer, is secreted by the inner florets, and as insects pass quickly from floret to floret in search of this, their bodies become covered with pollen, and they repay the plant for the food they obtain by effecting cross fertilization. Let us carefully watch the flower on a sunny day and observe how successful it is in attracting insect visitors. I have taken upon it and have now in my collection three species of bees, one butterfly, a small brown species of miller, three hemiptera, five flies, and seven beetles, or twenty species in all, a large number for the month of May. Butterflies are rarely met with, for as the honey is fully exposed and not concealed in a deep pit, as in the pinks, the flowers are adapted only to the visits of short lipped insects such as flies and beetles. Upon the open flowers they can readily obtain both honey and pollen, and in consequence are the most frequent visitors.

In gathering honey from the flowers of the hobble bush there would seem to be no possible danger to insects, and yet they not infrequently meet with a tragic end. Here lying upon the flat top of the blossom is a dead fly. Lift it up and you will discover how it was killed. The head is firmly grasped by the mandibles of a white spider, which, rather than release its prey, permits itself to be dragged from its hiding place and deposited in your collecting box. Except for a red lateral stripe on the abdomen, its color closely resembles that of the flowers amid which it lives, and of whose power of attracting insects it has learned to make use for its own benefit. I have never been able to observe this spider in the act of seizing insects, but I believe it catches them while they are sucking honey. A member of this same family of spiders also frequents the pyramidal flower clusters of the hardhack, and I have known of its capturing so large and strong an insect as the hive bee.

In a previous article I referred to the habit of bees of puncturing the spur of the yellow jewel weed (Impatiens fulva), to obtain the honey more easily than by entering the saclike flower in the legitimate way. In like manner bees puncture the two lipped tubular flowers of the common skullcap (Scutellaria galericulata). In two instances a narrow slit was observed on the upper side of the curved corolla tube, and in a third case the whole upper portion of the tube was cut away, leaving the lips suspended by a mere thread. The buds while still quite immature are also punctured at the apex, usually on the under side. The piercing of nearly mature buds has been recorded of Lamium album, but never before, so far as known to the writer, of the skullcap. The perforation of the flowers of the Labiatæ by bees is, however, of common occurrence. Both the maxillæ and mandibles appear to be employed, the former for piercing and the latter for biting away the tissue, and both the bumble and hive bees are known to make use of the holes in extracting honey. If, after the manner of certain plants famous in myth and story, the Impatiens (fitly, in this respect, named touch-me-not) could speak, what a protest it would utter! For unknown centuries it had been developing the color and form of its flowers, only at last to find its work in danger of being rendered worse than useless by a change in the habits of its bee visitors. It should, however, be mentioned that the flowers in North America are visited by humming birds, and I have also seen another smaller species of bee enter the flower in search of pollen.

THE IGUANAS IN THE ZOO AT LEIPZIG.

Of the many wonders which the Zoological Gardens of Leipzig offer to the gaze of visitors, a pair of fine iguanas form a principal feature, attracting at once the attention of scientists and laymen alike. We reproduce a cut from Illustrirte Zeitung, which their artist drew from life, and which gives a very good idea of the external appearance of the giant lizard—for of the family of the saurians, the iguana is a member.

In technical language, the animal is called Iguana tuberculata, the first part of the name being derived from the language of the natives of Hayti, where iguanas are found; the second, of Latin origin, referring to the excrescences on the head and neck (tuber, a boil, from tumeo).

The head is large and square, the neck is short and strong, the body is long and flattened out sideways, and ends in the long tail, which is covered with sharp scales. All over the body, along the spine, a sharp pointed comb runs from the back of the head to the tip of the tail, giving the beast a dragon like appearance. This is rendered yet more striking by the baggy skinfolds at the throat, which also are set with thorny scales. The whole body is thoroughly protected against the attacks of such enemies as the iguana is likely to meet.

The head is incased in scales which are partly flat, partly convex, lumpy or ridged. The rest of the body has feebly ridged scales. The ears are large and freely attached to the head. The animal often attains a length of 5 feet, over 3 feet of this total being taken up by the tail. This tail is by no means a useless ballast, but is used both as a means of propulsion and for steering when the iguana takes to water, where it is quite as much at home as in the forest. Here, in climbing, in leaping after food from branch to branch and from tree to tree, it avails itself of its strong feet, with their long, sharp claws, and by them becomes a truly dreadful foe to the small birds and lizards of which it occasionally makes a repast.

Examination of the stomach of these animals has shown that, as a rule, they live on vegetable food. Still, there were found among the contents of the stomach, besides remains of small birds and lizards (which we mentioned above), eggshells and small animals of various description.

The iguanas are vicious, wily, but show staunch resistance when attacked. In defense they use their pointed, back-curved teeth, and slash with their tails, blows from which are rendered dangerous by the sharp comb.

The male iguana choses a partner once, and does not quit her after. He will protect her against any other animal, and fiercely assert his privilege in having secured her favor.

The females lay their eggs on sand banks, carefully bury them in the sand, and pay no further attention to them. The heat of the sun, in time, calls the young iguanas from the soft-shelled eggs.

THE IGUANA IN THE ZOO AT LEIPZIG.

To hunt these lizards a gun is useless as a rule, for they can stand a heavy charge of shot, and once warned are soon safe, either in water or dense foliage. A more certain means of laying them low is an Indian arrow, which is often deadly. Dogs also are trained to bring to bay this queer prey. Animals secured are brought to market, where they are sold at a good price, to be consumed on the boards of wealthy people.

In captivity iguanas at first prove vicious, and snap at their keepers. They must be kept fairly warm, and the temperature around them must be constant, else the climate soon tells upon, and their life is ended by an untimely death.

To get them accustomed to the feeding, it is usual to worry them till they open their mouths, then the food is brought under their teeth, and, once bitten, is soon devoured. In time the persuasive power of hunger proves stronger than the stupefaction caused by the unaccustomed surroundings, and no further trouble is given in that respect.

THE REPRODUCTION OF THE EEL.

By HENRY DE VARIGNY in La Nature.

ONE of the problems that has occupied the attention of naturalists from the time of Aristotle up to the present is the method of reproduction of the eel. It is not because there has been any reason for the belief that this fish multiplies by processes different from those of other living beings, but because the conditions under which the fertilization of the egg is accomplished and where it is hatched have not been known, and because, too, it has never been possible to obtain the fry of this fish. The problem has now been definitely solved by the researches of Prof. G. B. Grassi, of Rome, and of his pupil Signore Calandruccio. The results may be summed up as follows: The fact that eels introduced by man into ponds and lakes that have no communication with rivers and the sea do not reproduce, and that no young are ever observed therein, has led to the idea that reproduction does not take place in fresh water, and the admission has had to be gradually made that the eel proceeds to the operation of multiplication in salt water. There would be here a migration similar to that made by the salmon and shad, but in inverse order, the latter, inhabitants of salt water, ascending fresh water streams to spawn, and the former, an inhabitant of fresh water, going out to sea to reproduce its kind. This view, à priori, finds some confirmation, moreover, in the fact that the only young eels that are met in rivers are always making the ascent thereof. They ascend, but do not descend streams, and they seem to come from the sea.

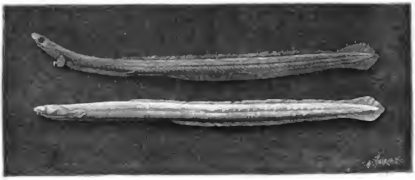

FIG. 1.—YOUNG EELS.

The eel therefore appears to reproduce itself in salt water; but where? And how is it that young eels are never found anywhere upon the coasts?

An interesting fact pointed out by Prof. Yves Delage, of the Sorbonne, some eleven years ago, ought to have put investigators upon the track. This fact was that a certain fish captured in the vicinity of Roscoff, and kept in captivity, changed into a conger, or sea eel. This fish belonged to a well-known group, that of the Leptocephala. This group has been a puzzling one, since the fishes that compose it seem to be incomplete, and they have a larval appearance. Their very small head (whence their name), the absence of scales, the slight development of the osseous skeleton, the absence of red corpuscles in the blood, and the general feebleness of their locomotion, all seem to indicate that these fishes, which are divided into several species by systematic zoologists, are young and not adults. In 1861 it was thought that they might be the larvæ of Cepola. In 1864 an American naturalist placed them in the family of eels, but Günther, in 1870, contended against these views in taking as a basis the fact that the Leptocephala are of larger dimensions than the young eels that ascend streams, and he regarded them as monstrous larvæ.

The transformation observed by Yves Delage, however, clearly showed where the truth was to be found, and Messrs. Grassi and Calandruccio resolutely entered the path opened by the French naturalist. Their success has been complete, and they must be congratulated upon it. Through them we now know that the fishes of the family Murenidæ first pass through a larval stage, and that the Leptocephala are nothing but the larvæ of Murenidæ. The Leptocephala therefore disappear, both as regards genera and species. They have no longer any zoological civil state and no longer form a systematic group, any more than do the tadpoles of the Batrachians or the caterpillars of the Lepidoptera; and the fact observed with regard to the common conger eel has likewise been observed with regard to several Murenidæ, and particularly the common eel.

The eel which interests us more particularly goes out to sea to reproduce its species. It does not, however, proceed everywhere to the work of reproduction, but makes a selection from among the innumerable sites that the sea offers it, and invariably takes refuge in the depths. It requires water having a depth of at least 1,000 feet. Is this a matter of taste merely, or is it because the eggs develop properly only under great pressures? This point is not yet elucidated. Among the localities where the conditions are found favorable in proximity to the coast may be mentioned the strait of Messina. Eels evidently visit this locality in large numbers, since the strong currents here often bring eggs and Leptocephala to the surface. In 1895 Prof. Grassi found the latter here by thousands; and when the currents are gentle, an almost certain method of procuring them consists in opening the easily captured Orthagoriscus mola. This fish, which inhabits the deep sea, always contains a few larvæ of Murenidæ in its digestive tube. These larvæ are met with from February to September and have long been known. They have been called by the name of Leptocephalus brevirostris, and it is they that are the young—the larval form—of the common eel, Anguilla vulgaris.

The accompanying figures, which we owe to the kindness of Prof. Grassi, represent the leptocephalus under consideration. It is from 2⅜ to 2¾ inches in length; and the extreme height of its body, which is very thin, forms a striking contrast with the somewhat cylindrical shape of the young eel. There is no doubt, however, of the connection between the leptocephalus and the eel. Prof. Grassi has directly observed the transformation of the leptocephalus in an aquarium, and, although the young eel is always shorter than the leptocephalus whence it proceeds, that is due to the fact that the latter, during its transformation, does not take any food and necessarily diminishes. While from the view point of external form the leptocephalus differs very greatly from the eel, there is, on the contrary, a complete concordance in the internal anatomy. The myomeras, the vertebral arches and the spinal ganglions are of the same number in each, and the rays of the pectoral fin of the leptocephalus are of the same number as those of the corresponding fin of the eel. We cannot enter here into the technical details given by Prof. Grassi, notwithstanding their interest; but it is well to remark that such interest is rather of a general order. While it is well to know what modifications occur or do not occur in the leptocephalus, it is not necessary to be acquainted with them in order to ascertain whether such transformation really takes place, since, through Prof. Grassi's direct observation, we know that the change occurs, and that the leptocephalus becomes a young eel.

In order briefly to recapitulate the history of the reproduction of the eel, we shall say, then, that the latter descends the rivers from October to January (in Italy at least) and that it reaches the deep sea, where (according to specimens occasionally thrown up by the currents) it undergoes evident modifications. Its eyes acquire dimensions that they never possess in fresh water, and it reaches sexual maturity, a thing that never occurs in rivers, nor in captivity, where we nevertheless find eels of 8 to 12 inches in which the sexual products do not succeed in developing. Reproduction takes place in deep water after the eel has lived therein for some time (a few months), and the pressure and

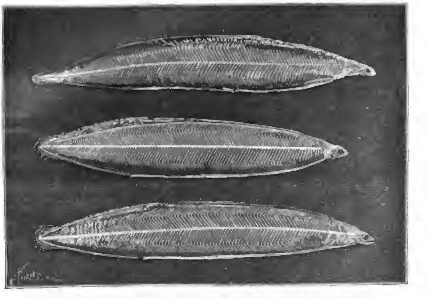

FIG. 2.—LARVA OF THE EEL (LEPTOCEPHALUS BREVIROSTRIS), STILL RELATIVELY YOUNG.

chemical constitution of the medium (and perhaps also other factors that escape us) evidently play a great part in the development of the sexual aptitudes. Eggs are found from the month of August to January, and the Leptocephali show themselves from February to September.

The duration of leptocephalic life is unknown. It is known, however, that a month is sufficient for the transformation into a young eel. It is Prof. Grassi's opinion that the young eel, that which ascends the rivers in spring, is already a year old; but of this year how many months belong to the larval state? This is a point to be cleared up.

And what becomes of the eel that has reproduced its kind? The general opinion is that it dies; that it does not return to fresh water, but ends its existence in the sea shortly after spawning. Such is the opinion given by Cunningham in his excellent "Natural History of the Marketable Marine Fishes of the British Islands."

This is very likely, moreover, since in fresh water we never find eels having the appearance of those that have lived in the sea, and most certainly if the latter returned to the rivers they would, for a time at least, preserve the peculiar character of the eyes that they had acquired in salt water.

Prof. Grassi has therefore very completely solved the problem of the eel; but we must say that he has not stopped here, for he has also studied the problem of other Murenidæ (Congromuraena mystax and C. Balearica, Ophichthys, Nettastoma, Saurenchelys, etc.), and, through a comparison of the larvæ and adults, has been able to show that all of the Murenidæ studied (save two, Chlopsis bicolor and Myrus vulgaris) first pass through a leptocephalic larval stage.

The details of these researches will be found in a memoir that he is publishing, but it has appeared to us useless to await this publication in order to make known the valuable work done by the Roman zoologist and his magistral elucidation of a problem that has defied so many naturalists.

In connection with the subject of the reproduction of eels, it may be of interest to note that the belief once universally entertained that eels present no distinction of sex seems to have been shared by the Massachusetts and Narragansett Indians, who, respectively, called the common fresh and salt water eels (Anguilla Bostoniensis) Nequttikaug and N'quittecounaug, dialectic variations of the same word, meaning "they go singly," or "one by one."

The Narragansetts, however, observed that there was at least one kind of an eel that apparently mated, and named the fishes of this species Neeshauog, meaning "they go in pairs." This name has been perpetuated, locally, in Massachusetts, in the form Neshaw, as the popular appellation for an eel that is sometimes taken in the salt ponds of Martha's Vineyard, and that Dr. Storer (Report on the Fishes of Massachusetts) supposes to be the silver eel (Murena argentea).

The fishes so designated by the Indians may have been sea lampreys (Petromyzon Americanus), the sexes of which usually ascend rivers in pairs, aid each other in piling up heaps of stones among which to spawn, and frequently exhibit evidences of mutual attachment.

UTAH UINTAITE DEPOSITS.

THERE has been published in the New York Tribune part of the seventeenth annual report of the United States Geological Survey, giving an account of "The Uintaite (Gilsonite) Deposits of Utah," and prepared by George Homans Eldridge. The name uintaite was given by Prof. W. P. Blake in 1885 to a variety of asphalt found in the vicinity of the Uinta Mountains in Utah. The name gilsonite, of a later derivation, was adopted because the substance was brought into prominence as an article of utility through the efforts of S. H. Gilson, of Salt Lake City. The trade knows it better by the latter name.

According to Mr. Eldridge, uintaite is employed chiefly in the manufacture of black, low grade brush and dipping varnishes, such as are used on the various kinds of iron work and as baking japans. It is employed by one company for mixing with an asphaltic limestone in the manufacture of paving material. Other uses, according to E. W. Parker, in "Mineral Resources of the United States" for 1893, are: preventing electrolytic action on iron plates of ships' bottoms, for coating barbed wire fencing, etc., for coating sea walls of brick or masonry, for covering paving brick, for acid proof lining for chemical tanks, for roofing pitch, for insulating electric wires, for smokestack paint, for lubricants for heavy machinery, for preserving iron pipes from corrosion and acids, for coating poles, posts and ties; for torpedo proof pile coating, for covering wood block paving, as a substitute for rubber in the manufacture of cotton garden hose, and as a binder pitch for culm in making briquette and eggette coal. Mr. Eldridge is inclined to believe,

however, that the uses of gilsonite as thus enumerated by Mr. Parker are in most instances still in the experimental stage.

In his paper, Mr. Eldridge treats of the classification of hydrocarbons and allied substances, chemical relations between hydrocarbons, resemblances and differences between the asphaltites, analysis of uintaite, geology of the Uinta Basin, and its topographical features, distribution of uintaite and allied hydrocarbons in the Utah fields, of the various uintaite veins, estimated tonnage of the uintaite fields of Utah, the exploitation of the veins, and commercial considerations.

The veins are known as the Duchesne, Culmer, Seabolt, Bonanza, Cowboy and Black Dragon. The most important locality of uintaite or gilsonite is the region immediately north and south of the White River, near the eastern edge of the Uncompahgre Reservation. The veins are here known as the Little Bonanza, Big Bonanza and Cowboy; they have not yet been exploited. The Duchesne vein, which lies near to and is named after Fort Duchesne, has been worked for several years, and is opened to a depth of 105 feet. The St. Louis Gilson Asphaltum Company controls the greater part of this vein, and has shipped a comparatively large amount of gilsonite in the five or six years it has been operating.

The Culmer and Seabolt veins cross the western edge of the Uncompahgre Reservation in the vicinity of the fortieth parallel. Only the Culmer is workable of these two, and this at a great disadvantage. The Black Dragon vein is situated in the region of Upper Evacuation Creek, and is one of great promise. The total tonnage contents of all these uintaite veins is estimated at 28,744,582. Mr. Eldridge says: "Mining for uintaite will be conducted after the ordinary methods, by means of shafts and tunnels. With the establishment of hoists and conveying machinery, of especial necessity will be the installation of a ventilating plant, for the dust derived from the gilsonite in mining is exceedingly annoying, penetrating both skin and lungs, and there remaining, except under the action of a solvent, impossible, of course, in the latter case. This peculiarity of the mineral is due to its insolubility in water, and to its softening under the temperature of the body. From the skin of the miner gilsonite dust is commonly removed by the application of kerosene oil. Besides the harmful results in breathing it, the dust has proved a dangerous element in mining, being highly explosive when its mixture with atmospheric air acquires a certain ratio, and it is then disturbed by the accidental fall of a lighted candle through it. Safety lamps can be used only with difficulty, on account of the heat melting the substance and forming a film over glass or gauze. Thus far ventilation has not been attempted, the men using aspirators, sponges, or other methods, the dust of the mine being laid once a week by spraying the walls with water, which finds its way to a sump and is raised in buckets."

COMMERCIAL CONSIDERATIONS.

The region within which the uintaite (gilsonite) veins occur is deficient in transportation routes. From the north it is inaccessible except by very indirect roads. To the south it is separated from the valley of the Grand and Price Rivers by the rugged Roan or Book Plateau and its canyons, though the travel of to-day is in this direction, the product of the Culmer and Duchesne Mines being taken by wagon to Price, on the Rio Grande Western Railway. Up Strawberry Valley and across the Wasatch Range the route is somewhat more difficult than the last, and the distance to railroad is considerably greater. The mines in the edge of Colorado now ship their product by wagon over a circuitous and hilly road, via Meeker, to Rifle, on the Denver and Rio Grande Railroad, 125 miles. It is thought possible, however, by those familiar with the country, to find a feasible route 50 to 70 miles shorter than this directly southward along the State line. The Bonanza and Cowboy group of veins is a little more remote from Rifle than are the Colorado openings, though, perhaps, attended with no greater difficulties of transportation. By the way of Fort Duchesne to Price the route from these veins is about 180 miles. The vein of uintaite (gilsonite) on Upper Evacuation Creek is, perhaps, a little more inaccessible than any of the others, unless it should be proved possible to establish a route directly south across the Roan or Book Plateau, when it would become the nearest of all the deposits to railroad communication.

The cost of freighting the product of the Duchesne and Culmer mines to rail is now $12 to $15 per ton. Railway freight to Chicago is said to be about $9 per ton. The total cost of mining and placing the material in Chicago or St. Louis is therefore not far from $25 per ton. Office and management expenses may increase this to $30. The present price per ton in Chicago and St. Louis for the best grade is $40 to $50, leaving a net profit of $10 to $20. The factors in a reduction of the price to the trade will be railroad transportation direct from the Uinta Basin, which seems probable at a future day, and competition, which will arise should any equable distribution of mining claims be made among the numerous companies that will doubtless be inclined to work these great deposits.

SOME ADVANTAGES OF GILSONITE.

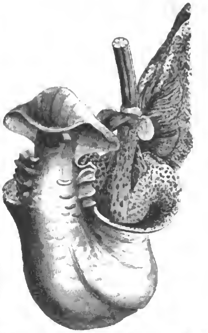
By some manufacturers the use of gilsonite in preference to other asphalts is considered advantageous from the standpoint of economy, as it is said to require less linseed oil to obtain equally satisfactory results, to have a greater capacity for the thinning medium with correspondingly less deterioration from its use, and to maintain an equal bulk of product with employment of a smaller percentage than of other asphalts.

The present cost of varnishes of the first quality made from gilsonite is about $1.25 per gallon, and somewhat lower for lower grades. From the evidence gathered by Mr. Eldridge, the opening of the gilsonite veins and competition among mining companies would tend to lower the price of the raw material to manufacturers, but many of the latter do not believe an increased supply of this would materially lower the price of the varnish, as competition has already brought this to a limit. There would result, however, an improvement in quality among those who are now inclined to adulterate with resin, and the foreign asphalts used for the same purpose would be driven almost entirely from the markets of the United States. The quantity of gilsonite used by varnish manufacturers would also doubtless be considerably increased, but the total consumption for this purpose would always be comparatively small, for among even the larger concerns a carload often lasts six months.

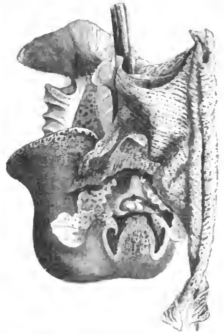
In the manufacture of paving cement, gilsonite of the second grade is melted with petroleum residue in a tank similar to that used for its liquefaction with linseed oil for use in varnish making. To the heated mixture is added ground asphaltic limestone carrying, perhaps, an average of 18 to 20 per cent. asphalt. After thorough mixing and heating, the material is drawn from the tank into barrels and stored ready for shipment. For paving it is remelted, the requisite amount of sand is added, and the mixture is then spread like the ordinary asphaltic paving material in such wide use in the larger cities.

THE CORYANTHES.

The members of this extraordinary section of the Stanhopea tribe, which are found rather widely distributed in tropical America, have been known to science for upward of three-quarters of a century. Although the plants have remained uncommon, the limited number of them which have flowered in gardens have caused more wonder and admiration by reason of the extraordinary structure and general dissimilarity to other flowers than have any of the showier and more popular species and genera. Every portion of the floral structure in Coryanthes affords proof of the correctness of the theory that orchid fertilization is brought about by insect agency, and what was conjectured from a study of the plants under cultivation has been fully substantiated by such careful observers as Dr. Crüger, formerly director of the botanic gardens, Trinidad; Mr. J. Rodway, F.L.S., and others, whose investigations were published in former issues of this journal.



CORYANTHES FIELDINGI—FRONT VIEW OF FLOWER.



CORYANTHES FIELDINGI—BACK VIEW OF FLOWER.

The Coryanthes are strictly epiphytal, and it was noted by importers that the specimens obtained by collectors were mere tufts of pseudo-bulbs proceeding from long oval masses of roots, and with scarcely a particle of moss or other substance or growth about them. These suspended masses were, according to the collectors, the homes of innumerable ants, and it was even asserted that the presence of the ants was essential to the well-being of the Coryanthes. This, however, as Mr. Rodway explained, is only another of Nature's wise provisions—the massed root growth of the plant supplies a congenial home for the ants, who in return attack the numerous other insects which would injure the plants, and thus in exchange for lodgings give protection.

Our illustrations of Coryanthes Fieldingi (Figs. 1 and 2), one of the oldest but still one of the most rare species, will indicate the size that the flowers of most of the Coryanthes attain. The structure of the flower is exceedingly strange, and not the least remarkable feature about it is the contrast between the membranous sepals and petals and the thick fleshy labellum, the former soon curling back into comparative insignificance, leaving the large and complicated lip as the chief attraction. As soon as the flower expands a strong and penetrating odor is emitted, and, to quote Dr. Crüger's words, "large humble bees, noisy and quarrelsome, are attracted at first by the odor; but this probably only gives notice to the insects. The substance they really come for is the interior lining of the labellum, which they gnaw off with great industry. They may be seen in large numbers fighting with each other for a place on the hypochile. Partly by these contests, partly perhaps intoxicated by the substance they are consuming, they tumble down into the bucket (epichile), which is half filled with the fluid secreted by the horn-like organs at the base of the column. They then crawl along the anterior inner side of the bucket, where there is a passage for them. If one is early on the lookout—for these Hymenoptera are early risers—one can see on every flower how fecundation is performed. The humble bee, in forcing its way out of its involuntary bath, has to exert itself considerably, as the mouth of the epichile and the face of the column fit together exactly, and are very stiff and elastic. The first bee that is immersed will have the gland of the pollen masses glued to its back. The insect then generally gets through the passage, and comes out with this peculiar appendage, to return nearly immediately to its feast, when it is generally precipitated a second time into the bucket, passing out through the aperture, and so inserting the pollen into the stigma while it forces its way out, and thereby impregnating either the same or another flower. I have often seen this, and sometimes there are so many of these humble bees assembled that there is a continual procession of them through the passage specified."

The above remarks related to Coryanthes macrantha, but they apply equally to other species. The congregating of the insects takes place on the cap above the ribbed mesochile, and the fall of the insect into the bucket, and its passage out, during which the act of fertilization takes place, is shown by the position of arrows.

The genus was founded by Sir W. J. Hooker in 1831 on C. maculata, joining with it C. speciosa and C. macrantha, which had previously been known as Gongora, and at different periods some ten or a dozen other species have been added. The prevailing colors of most of them is yellowish, with crimson and purple markings; though, as in the case of the C. maculata vitrina, imported by Messrs. F. Sander & Company, which is wholly greenish-yellow, varieties have appeared in which the colored marking is suppressed.

A plant of C. macrantha flowered recently with J. H. Kitson, Esq., Elmet Hall, Leeds (gr., Mr. T. Bonsall). A flowering plant of C. elegantium was figured under the name of C. macrantha in Gardeners' Chronicle, May 6, 1882, pp. 583 and 597.

Of comparatively recent introductions, five remarkably beautiful species may be specified, viz., C. macrocorys, distinguished by its slender, ungrooved mesochile and narrow and long hood; C. leucocorys, with rich purplish crimson bucket and pure white hood; C. Bungerothii, a rich yellow lipped species, spotted inside the lip with bright crimson, and in which the hood is prolonged over the neck-like mesochile, like a cape; C. Wolfii and C. Mastersiana, both of which are described by Consul F. C. Lehmann as of a new section of Coryanthes, with stout, ascending inflorescence, in the Gardeners' Chronicle, October 24, 1891, p. 483. The former has flowered in the Royal Botanic Gardens, Glasnevin, Dublin, and proved a very fine species.

Coryanthes, being epiphytal plants, require to be grown under cultivation in baskets, and with no great bulk of material, such as peat or sphagnum moss, around them. During growth an unlimited supply of rain water should be afforded, and the plants should be placed in a warm, moist, but airy house. After flowering is past, the condition of the Mexican house is best suited to their needs, but at no period should they be exposed to cool treatment. At the same time there is every reason to believe that the scarcity of the plants in gardens is mainly due to their being kept continually in the same excessively warm and too often ill ventilated house. It should be borne in mind that, whether growing in hot or cool houses, all orchids require ventilation.—J. O'Brien.

CORYANTHES LEUCOCORYS.

This species well shows the peculiar structure of the genus. A plant is now in flower in the botanic garden, Edinburgh, carrying one flower upon the pendulous

scape, which springs from the base of the furrowed pseudo bulbs. They are short lived; the sepals soon collapse, and, indeed, the whole flower lasts but three or four days. The principal attraction in the flower is, perhaps, the immense helmet-like structure into which the secretion drops—this being of a pale coral pink, and the ivory hood white. The plant has been grown in an unshaded part of a pit devoted to Nepenthes, and in this position it is well suited. A figure of this species is to be seen in Lindenia, t. 298; its habitat is Peru.—R. L. H., The Gardeners' Chronicle.

ARE MEN OF GENIUS DEGENERATES?

The theory of Lombroso, that genius is a form of degeneration, is opposed in the Revue des Deux Mondes (Paris, June) by M. G. Valbert. The Literary Digest translates as follows: After telling us that the Italian scientist has "passed his life in searching for and discovering cruel truths," the critic goes on as follows:

"The last of his [Lombroso's] discoveries is perhaps the most alarming, and he speaks of it with relish. It is with true enjoyment that he endeavors to persuade us that if alcoholics, criminals, cretins, and deaf mutes are degenerates, the great men are their cousins german, that genius is a sort of degenerative psychosis, belonging to the family of the epilepsies. . . .

"Lombroso believes that, after all, his theory has its consoling side; there comes to its aid the system of compensations, which has decreed that every advantage that is acquired shall have its drawback and that every gain shall be accompanied by a loss. 'The reptiles,' says Lombroso, 'have more functions than we, the monkeys have a greater number of muscles and an entire organ—the tail—that we lack. Only by losing these advantages have we gained our intellectual superiority.' The man who succeeds in convincing himself that his mind would fall suddenly to a lower scale if he had a tail, quickly consoles himself for not having one, and when we show that genius is a psychosis, we reconcile to their lot all minds that are mediocre or less than mediocre. They will even congratulate themselves that they have no kind of talent, for, according to Lombroso, 'the man of talent, even of genius, presents slight but real anomalies, which give occasion for injurious pathologic reactions whose traces are found in the tendency of his children to degenerate.' . . .

"But it is not sufficient to affirm that the theory of the psychosis of genius is a consoling truth; it is necessary to demonstrate that it is true, and people who are difficult to please will think perhaps that, when it comes to proof, Lombroso is satisfied with very little. This medical alienist, with his experiments and his skill, is a laborious compiler of anecdotes, which furnish him his strongest arguments. Some are curious, others are suspicious; most are less conclusive than he thinks."

After quoting a number of typical anecdotes and giving a brief sketch of Lombroso's ideas, most of which are already familiar to our readers, M. Valbert resumes his criticism as follows:

"The morose critics of whom I have spoken will perhaps complain that there is a good deal too much that is arbitrary in Lombroso's reasoning. He begins by asserting that the normal man is he who uses his mind only to gain his daily bread; it follows that men of superior intelligence are encroaching in some degree on common rights, that genius is a perversion and anomaly, and every anomaly is a case of disease. It is certain that men of genius do not abound, and if we are speaking only of great statesmen, Nature thinks she has done well if she produces three or four in a century. But M. Lombroso has a short memory; he forgets his first principles till they turn against him and confute his paradoxes. He declares that there are no exceptions in the world, that by virtue of what he calls the 'serial law' of his beloved statistics no phenomenon is produced that is not the expression of a numerous series of analogous facts, less distinct and less apparent. We may conclude from this that genius also is but the last term of a series. Numbers of men who have it not yet possess in a rudimentary state some of the qualities that it unites in all their glory—we may call these 'genial' men, and they have this advantage, they are very easily studied; they are petty suns that we may look at directly, without being dazzled; they do not oblige us to shade our eyes.

"There are 'genial' men in all ranks of society, in all classes, in all professions, in the country as in the city, and often amid the poor and humble. . . .

"But let us talk now only of the real genius . . . whether he paints or builds, whether he is sculptor or poet, whether he composes symphonies, epics, or dramas, whether he guides the destinies of a great people or leads armies in the field; we admire, equally with the extent of his thought and the grandeur of his conceptions, the justice of his view, the close connection of all parts of his work, the harmonious complexity of his designs and the simplicity and wisdom of his processes, the deep sagacity which, loving the real and the possible, sacrifices to them all chimeras, the rhythm of a will always regulated and always even, the obedience of a powerful imagination that consents to let itself be ruled by a sovereign and impassible reason.

"'These are degenerates, I tell you!' cries M. Lombroso from Turin, 'and you may be certain that many of them have protruding ears, an asymmetric visual field, and the handwriting of an epileptic or a lunatic!' We must not suppose that he is making fun and that he is putting our credulity to the test. This would be unfair to him. I believe in his seriousness as much as I doubt the infallibility of his methods. Has he his hours of doubt? Do disquiet, remorse, ever attack him? . . . Who knows? In his chapter on 'mattoids' he tells of a learned professor whose taste ran to enormities and who maintained that sea water owed its medicinal virtues to the expiration of fishes. 'And nevertheless his works,' he adds, 'contain very fine things and have reached a second edition; none of his colleagues ever suspected him of insanity. In what class shall we place him? Certainly in a rank midway between the insane person, the man of genius and the graphomaniac; with this last he has in common sterility of object, and the calm and steadfast investigation of paradoxes.' M. Lombroso is imprudent; does he not fear that some of his readers will suspect him of having doubled on himself and of applying the rod to his own back?"—Translated for the Literary Digest.

THE NEW BUILDING.

NEW MASSACHUSETTS STATE LIBRARY BUILDING, AT BOSTON, MASS.

THE NEW MASSACHUSETTS STATE LIBRARY BUILDING, AT BOSTON, MASS.

WE present in this issue, on first three pages, engravings illustrating the new extension to the Massachusetts State Capitol at Boston, Mass. The corner stone of the old Capitol building, a view of which can be seen at the left of the picture, was laid on July 4, 1795. This building, usually spoken of as the "Bulfinch building," derives its name from the fact that Bulfinch, the first and one of the greatest American architects, designed it, and it has always been considered his masterpiece. The facilities of this building having been inadequate for many years, it was decided that the sadly needed room for the various departments of the State government be enlarged, and in 1889 the construction of the extension was authorized, and land was taken for the purpose in the rear of the Capitol, on the north slope of Beacon Hill. The corner stone of this building was laid with appropriate exercises by Gov. Ames, on December 21, 1890. The design was intended to harmonize with the Bulfinch front, and this idea is carried out in detail; but when you take into consideration that the new structure is more than twice the size of the Bulfinch building, you will readily see that it greatly dwarfs the latter, and that the effect sought has not been materialized. When the commissioners in charge of the construction in 1894 realized this defect, they very rapidly urged the demolition of the old Capitol building and to construct an entirely new one. This proposition naturally raised an indignant and universal protest throughout the commonwealth, and when an attempt was made to pass a bill through the Legislature to demolish this old Capitol building, rich in its style of architecture, with its colonnaded front and gold crested dome, standing as it does with historical interest upon a site overlooking the famous Boston Common, and making a picture which is dear to the heart of every true Bostonian, it was rejected by the Legislature, and the patriotic sentiment of the commonwealth won a victory over that of vandalism; hence the preservation of the old State House. There is a strong feeling that the reconstruction of the old part, made necessary by new conditions, should proceed with the most thoughtful regard for the spirit of Bulfinch's historic design, while making such changes as are essential to protect it against any ill treatment or injurious effects. The new extension which we present, and more particularly use as an illustration, is constructed of yellow brick, with white marble trimmings, simulating the familiar yellow and white of the colonial style. The underpinning is built of rock faced stone, the first story of dressed stone, and the remainder of the structure of brick, while the whole is surmounted with a massive frieze and balustrade. The only necessary requisite in a building of this character is the necessary apartments and their respective dependencies, and in the present case the actual and most essential requirements have been secured, and while the architecture is of a classic order, it is of the simplest expression; and how very effective an expression it is, when you take in consideration that the building was designed in keeping with the old building, and the general scheme of style and color is carried out with consistency to the last detail. The absolute plainness of the basement, except the outlying porches, the treatment of which is still severe, gives value to the arcades above, which is still further enhanced by the absolute plainness of its inclosing wall. The highest merit of the detail is that all of it tends to promote a high expression, and is far more valuable in its place, owing to its proper adjustment, which has been studied with complete success with reference to its situation and material. The outcome of the study that has been devoted to this work in composition, modeling and ornament can safely be called a classic piece of architecture with Romanesque feeling. The interior of the extension is pleasant, cheerful, well ventilated, and convenient. It contains the various administrative and executive departments of the commonwealth, and includes two handsome halls, that of the House of Representatives and the State Library, besides various committee rooms. The Senate remains in its chamber in the old building. The new Hall of Representatives is a handsome and richly decorated room, considerably larger than the old hall. The amphitheater shape, with its domed ceiling, lends itself well to fine decorative effects. The treatment is in the Italian Renaissance. Some of the prominent features of the scheme are the names of fifty-three men, prominent in Massachusetts history, inscribed in the frieze, beginning with John Carver and ending with Phillips Brooks. The names of the counties in the stained glass skylight, and the symbols of statecraft, law, commerce, science, industry and art that occupy panels in the coving and elsewhere, are also good features. Five large panels on the wall are intended to be occupied by decorative pictures representing events of Massachusetts history. The next department of importance is the State Library room, of which we give illustrations. Owing to the modern architectural effort being toward permanency, a demand has necessarily risen for fireproof interior fixtures, and if perfect security is to be obtained, not only must an apartment be fireproof, but also all its fixtures and its furniture, its connecting doors, interior trim and protecting shutters. Up to a comparatively recent period, these could not be secured of non-inflammable material, except at a large cost and in an unattractive form. The question in regard to the safe custody of the public records has become a grave necessity, and while considerations looking toward their longevity are justly recognized as of such importance as in some cases to be prescribed by statute, the prime factor for their safety still remaining for absolutely safe quarters for their custody and protection. The commission of experts having had these ideas in consideration, they adopted a basis upon which such a means could be materialized, and it does so conform in every respect. As an example of perfection in metallic building for interiors, we present a few specimen illustrations of the interior of the new State Library, one of which is an interior view of the reading room, delivery counter, desks and stack work, of which a glimpse is shown through the opening at end of room, this metallic work being of the highest order. A more detailed view is given of the alcove cases, which are built up of steel plates, ornamented with solid bronze ornaments and mouldings, fitted with marble base, and the Fenton system of adjustable library shelving. The last view is taken from the gallery in the stack room, and presents what the Fenton Company claim as one of their most important products, a perfect system of metallic library stack work, embodying all the points of lightness, ventilation, strength and utility, which were called for in the specification of twenty-one requirements as the essentials in a perfect system of library stacks. This metallic work must come with peculiar interest to architects and the building trades who have in consideration works of this character. The metallic work in this building has cost $125,000, and it was designed and built by the Fenton Metallic Manufacturing Company, with general offices and works at Jamestown, N. Y., and a New York office at 621 Broadway. The Capitol has one of the finest heating and ventilating plants in the world, constructed according to plans under Prof. S. H. Woodbridge, of the Massachusetts Institute of Technology. Another feature of particular interest is the lighting with electricity, furnished by a large isolated plant. The library stack room is splendidly lighted by a system that is certainly unique. Each tier is lighted by turning a switch. In the usual system of lighting library stack rooms, the turning on of the current lights the lamps overhead, but in this State Library the wiring is done so that when the current is switched on the lamps underneath the glass floor are also lighted as well as those above. Thus the light shines up through the glass floor, rendering access to volumes on the lower range as easy as those in the middle. Those who have had occasion to use libraries which have been poorly lighted will appreciate this convenience. The buildings will have properly laid out parks surrounding same when completed, and which will add much value to the picture presented.

Our engravings were made direct from photographs of the buildings, taken specially for the SCIENTIFIC AMERICAN.

EXPERT TESTIMONY.*

By WILLIAM P. MASON.

IT will be remembered that a would-be facetious barrister once remarked that prevaricators might be properly arranged in an ascending series, to wit: ordinary fibbers, liars, and experts; an arrangement which I fear meets with the approval of many members of the bench and bar to-day. The cause for such harsh classification is not so very far to seek. It is based upon ignorance on the part of the bar, and at times upon what is worse than ignorance on the side of the "expert." With the culpable acts of the pseudo scientist we cannot waste our time. That he merits prompt condemnation is axiomatic; but a word is wanted touching upon what may be termed the ignorance of the court.

"When I take my place upon the witness stand," said a prominent toxicologist once to me, "I can never predict in what shape I shall be upon leaving it," a feeling with which most of us can, I fancy, sympathize pretty keenly.

Is it that we fear exposure of the weak points in our professional armor? Do we dread to say in public, "I do not know"? Hardly that, I take it. We are now possessed of so very little of that which one day may be known that no true scientist hesitates for an instant to plead legitimate ignorance. What really troubles us upon cross examination is that the court does not speak our language, a language often quite difficult of direct translation; that it is but rarely schooled in the principles of our science; and that, in consequence, it frequently insists upon categorical answers to the most impossible kind of questions.

The hypothetical questions showered upon the expert witness are sometimes veritable curiosities, so peculiar are they in their monstrosity. Who among us but has felt that the layman, who has simply to testify to observed facts, has an easy time of it indeed, when compared with him from whom there is expected an opinion under oath?

All scientific men are willing and anxious to have their work scrutinized carefully by their peers; but to be exposed to the one-sided criticism frequently encountered at the bar is quite another matter; for it must be remembered that after the adverse counsel has opened up what appears to be a glaring inconsistency in the testimony, the redirect examination may utterly fail to repair the breach, because of a lack of familiarity with a technical subject on the part of the friendly attorney.

This leaves the witness in the unenviable position of

* Address before the American Association for the Advancement of Science, August, 1897.

disagreeing with the general drift of his own testimony, while it deprives him of suitable means of insisting upon its revision and correction.

According to the writer's view, there is but one way to escape such dilemma, and that is by direct and immediate appeal to the judge; urging that the oath taken called for a statement of the whole truth and not the misleading portion already elicited.

To illustrate how serious a matter the partial testimony of an expert witness may be, and to show also to what extent lawyers may go who look only to the winning of their causes, permit me to refer to an already reported poison case in which I was employed by the people. It may be roughly outlined as follows:

Much arsenic and a very little zinc were found in the stomach.

The body had not been embalmed, but cloths wrung out in an embalming fluid containing zinc and arsenic had been spread upon the face and chest.

Medical testimony showed that no fluid could have run down the throat. Knowing the relative proportions of zinc and arsenic in the embalming fluid, the quantity of arsenic found in the stomach was twelve times larger than it should have been to have balanced the zinc also there present, assuming them to have both come from the introduction of the said embalming fluid by cadaveric imbibition. Other circumstantial evidence was greatly against the prisoner.

At the time of my appearing for the people, on the occasion of the first trial of the case, my direct testimony brought out very strongly the fact that a fatal quantity of arsenic had been found in the stomach, but no opportunity was given me to testify to the presence of the zinc found there as well, although the fact of its existence in the body was known to the prosecution through my preliminary report. Through ignorance of the nature of such report on the part of the defense, no change was made in the character of becoming acquainted with his whole story. Do not such differences in legal opinion make it very desirable that the expert, at least in capital cases, should be the employe of the bench rather than of the bar, in order that whatever scientific investigations are made may be entirely open to public knowledge and criticism?

Although the expert should earnestly strive to have what he has to say presented in the best form, he must remember that to secure clearness, particularly before a jury, technicalities should be reduced to a minimum. To a degree they are unavoidable, but let them be as few as possible. Illustrations should be homely and apt; capable of easy grasp by the jury's minds, and if possible taken from scenes familiar to the jury in their daily lives.

It is an unfortunate fact that the expert must be prepared to encounter in the court room not only unfamiliarity with his specialty, but also deep rooted prejudices and popular notions hoary with age and not to be lightly removed from the mind by the words of a single witness. As President Jordan has well said, "There is no nonsense so unscientific that men called educated will not accept it as science;" and, let me add, they will calmly attempt to shove the burden of proof upon the scientific man who is opposed to their views. Sanitary experts, in particular, run up against all sorts of popular superstitions and are inveighed against as "professors" by those who consider themselves the "practical" workers of the time; and, let it be noted, the burden of proof is uniformly laid upon these "professors'" shoulders, while the most astounding and occult statements made by the "practical" men may be received without verification.

One source of trouble, which perhaps is peculiar to the water expert, lies in the impossibility of utilizing analytical results such as were made many years ago.

Those who are not chemists fail to grasp the fact that carries. When the expert reaches a position of such prominence that he can state a thing to be so because he says it, irrespective of whatever may be written on the subject to the contrary, his course then is greatly simplified; but long before he attains that altitude he will have put himself upon record in many cases, and happy for him if the record so made be such as cannot be quoted to his disadvantage.

"If I had only not written my first book," is the reflection of many a distinguished author; while one of the great masters of music, referring to an opera, said: "It is one of my early crimes."

Above all things, the expert "should provide things honest in the sight of all men."

It is well for him to be deeply interested in his case, to feel in a measure as if it were his own, but it is unwise in him to become so partisan as to let his feelings affect his good judgment, and it would be indeed criminal should he permit his interest in any way to contort the facts.

Before the case is brought to a final hearing, it may be apparent that experiments before the court are possible and they may be demanded by the counsel in charge of the case. If such experiments be striking, easy of execution, and not too long, by all means make them.

Practical illustrations, particularly such as involve some fundamental principle, have great weight with the court; but these illustrations must not be such as would turn the court room into a temporary laboratory and involve the loss of much time in vexatious waitings.

Such experiments as are determined upon should be thoroughly rehearsed beforehand, no matter how simple they may be; for, of all failures, the court room experiment which declines to "go off" is perhaps the most dismal.

This brings to mind a kindred topic upon which there should be a word of caution; laboratory experiments,

VIEW IN STACK ROOM.

NEW MASSACHUSETTS STATE LIBRARY BUILDING, AT BOSTON, MASS.

my testimony during the cross examination, and I was permitted to leave the witness stand with a portion of my story untold. No witnesses were called for the defense, and the case was given to the jury with the darkest of prospects for the prisoner.

For many reasons, unnecessary to recount here, I was distinctly of the opinion that murder had been committed, but I felt, nevertheless, that common justice demanded that the prisoner should have been entitled to whatever doubt could have been thrown upon the minds of the jury, no matter how far fetched the foundations for such doubt might have been.

The first trial resulted in a disagreement of the jury. I was pleased to learn, before the second hearing of the case began, that the defense was prepared to go into the question of the embalming fluid; for the responsibility of permitting only a part of what I knew to be drawn from me, to the entire exclusion of the remaining portion, was greater than I wished to assume. The nature of my report to the coroner having been established, and certain opinions relating thereto having been fully ventilated, the jury were possessed of "reasonable doubt" and acquitted the prisoner. What now were the duties of the expert upon the occasion of the first trial of this case and how should he have construed the meaning of his oath?

One eminent legal light, to whom the question was referred, held that the expert was distinctly the property of the side employing him, and that his duty was simply to answer truthfully the questions put to him, without attempting to enlighten the court upon facts known to him, but not brought out by the examination, no matter how vital such facts might be.

Another held that although the above course would be proper in a civil case, yet, in a matter involving life and death, the witness should insist upon the court that the examination of water may not be looked upon from the same point of view as the analysis of an iron ore. The statement that water analysis is but of recent birth, and that it is yet in its infancy, is hard for them to appreciate, holding, as they naturally do, that what was true twenty years ago must be true to-day, if science does not lie.

A pit into which many an expert witness falls is prepared for him by insidious questions leading him to venture an opinion upon matters outside of his specialty. It is a fatal error to attempt to know too much. Terse, clear answers, well within the narrow path leading to the point in question, are the only safe ones; and when the line of inquiry crosses into regions where the witness feels himself not truly an expert, his proper course is to refuse to testify outside of the boundaries of his legitimate province.

Unfortunately the expert is as often invited to take these collateral flights by the side employing him as by the opposition. Affidavits in submitted cases are commonly written by the lawyers and not by the expert, although they are, of course, based upon his reports. In the strength of his desire to win the case, the lawyer often prepares a much stronger affidavit than his witness is willing to swear to.

The writer has had no little difficulty just at this point, and has had plenty of occasion to observe the irritation displayed by counsel upon a refusal to indorse statements which have been "too much expanded."

Every expert witness, especially in his early cases, is sure to have adverse authorities quoted against him; therefore it behooves him to be so familiar with the literature of his subject as to be capable of pointing out that such and such a writer is not up to date, or that such and such a passage, if quoted in full, would not bear the adverse construction that its partial presentation which work to perfection, may utterly fail when expanded to commercial proportions, so that it is wise to bear in mind the danger of swearing too positively as to what will happen in large plants, when the opinion is based only upon what is observed to occur upon the smaller scale. Like conditions will, of course, produce like results, but it is marvelous how insidiously unlooked-for conditions will at times creep into one's calculations, and how hard it is even to recognize their presence.

When preparing his case for presentation, the expert often errs in not dwelling more largely upon certain points because he thinks them already old and well known. To him they may be old, but to the public they may be of the newest. Not only is the public unequally posted with the specialist, but what it once knew upon the subject may have been forgotten. It is well, therefore, to insert, in a special report, matters that would be properly omitted from a paper prepared for a professional audience.

Sanitary problems are of especial interest to the public, but the amount of ignorance, or rather false knowledge, displayed concerning them is surprising and often difficult to combat. The sanitarian is not unfrequently called upon suddenly to defend a position involving complex statistics; and, because the data cannot be forthwith produced, the inference is drawn that his points are really without facts to support them and that they are consequently not well taken.

Long before he gets into court, particularly if the time for preparation of the case be short, the expert may well "pray to be delivered from his friends." He may receive a peremptory order by telegraph to "determine the mineral qualities of this rock," when the telegram should have read: "Assay this ore for silver;" and later it may be a matter of surprise that a quanti-

tative knowledge of the copper present was not obtained while passing along the line for the determination of the silver; for it is not generally known that the complete analysis of anything is quite rare and correspondingly tedious and expensive.

Toxicologists who hear me may call to mind some case involving a search for the presence of an alkaloid, strychnia for example, during which search, the district attorney, in his eagerness for information, may have asked to know what the indications were as to the presence of the poison, at a time when the extraneous organic matter was not nearly removed. He may have wished no final report, but only the simple probabilities, whereon to base a possible arrest. Such requests are very common, and are akin to a demand for a proof of the pudding during the early baking, when we all know that such proof comes at a much later stage of the proceedings.

Finally, "When doctors disagree, who shall decide?" This question is often very vigorously settled by the jury, as was instanced in a recent celebrated murder trial in New York City. In that case what the experts had to say on either side was simply thrown overboard as a whole, and the finding was based upon the testimony of the remaining witnesses.

What can be said upon this question of the disagreement of expert witnesses? First, it must be noted, they are far from being the only class of people who fail to agree, and that, too, on very important subjects. Do my hearers think it would be a very difficult task to find a small army of men who would testify very variously and very positively upon questions of politics or religion? Would it be hard to find "good men and true" who would give under oath greatly differing opinions concerning the propriety of instituting free trade or establishing an inheritance tax? Experts are subject to the same errors of judgment as befall the rest of professional humanity, and, when their opinions clash, they are entitled to the same respect that we grant to the members of the bench when they hand down the decision of a divided court.

One fruitful opportunity for disagreement always arises when questions are brought into court touching upon matters newly discovered and apart from the well beaten path of common professional knowledge. Doubt is often left upon the minds of those seeking the light, even when the testimony is given by the specialist who originally developed the new point in question, for one cannot be expected to be thoroughly educated in that which he has himself but recently discovered.

Many of us have dreaded to see the "ptomaines," or putrefactive alkaloids, make their way into court with their mystifying influences upon judge and jury and their tendency to protect crime. Now that they are in, what is to be the end? Even with no "ptomaine theory" possible, the ptomaine form of argument is not unknown. The writer was once asked in an arsenic case whether he was willing to swear that at some future time an element would not be discovered giving the stated reactions now called arsenical. Such nonsense is of course instituted to impress the jury, and is suggested by similar questioning in the alkaloid cases.

A recent and somewhat amusing instance arose from an attempt to introduce the rather new conception of "degeneracy" into a murder trial. The defense sought to show that the prisoner was a "degenerate," and offered expert testimony as to the meaning of the term and as to the signs whereby such a condition was to be recognized; whereupon the prosecution called attention to the fact that the defendant's experts themselves exhibited every one of the signs in question.

Having said all that he was to say, and having stated it to the best advantage, should the expert depend upon the stenographer so recording it as to allow of its being used in future without correction? Decidedly not.

The average stenographer is unfamiliar with technical terms, especially such as are chemical, and the witness who fails to supervise the minutes may find out later that he was sworn to a most remarkable array of "facts." The writer once discovered that he had recommended, as a very efficient method of purifying a city water, the filtering of the entire supply "through a layer of black mud." Not to take your time further, let us summarize what has thus been briefly said:

The expert witness should be absolutely truthful, of course; that is assumed, but beyond that he should be clear and terse in his statements, homely and apt in his illustrations, incapable of being led beyond the field in which he is truly an expert, and as fearless of legitimate ignorance as he is fearful of illegitimate knowledge.

Mounting the witness stand with these principles as his guide, he may be assured of stepping down again at the close of his testimony with credit to himself and to the profession he has chosen.

PERPETUAL MOTION.—I.*

The search after "perpetual motion"—so called—though centuries of vain effort have brought only failure, still captivates those who believe in the possibility of such a machine, exacting time and money from its votaries. To the end that it may be seen how hopeless are all such efforts, and that inventive genius may be turned into more profitable channels, we have decided upon publishing the present series of articles.

It is not designed to make these papers a connected history of the numerous attempts which have been made at solving this problem. Our object will be principally to place before our readers some of the most plausible devices that have deceived people into waste of time and money, that others may shun these false paths; for it is noteworthy that not one of the devices which have been brought to our notice by modern inventors, in the course of our long and large practice as patent solicitors, has not had its prototype in some invention that preceded it. "There is nothing new under the sun," said Solomon the wise, and certainly so far as "perpetual motion" machines are concerned, Solomon was right.

Many people are not very clear in their ideas of what is meant by "perpetual motion," and the term itself is one of those unfortunate ones calculated to mislead those who do not use language critically.

The perpetual motion so long sought by inventors is not something that moves or will continue to move forever, or that will move till it wears out. A water wheel placed on a never failing stream is a perpetual motion, if this be the true meaning of the term. Neither is it a machine that, once set in motion by an external force, will retain its motion forever, or until it is stopped by the action of another external force, though even such a machine has never been constructed by human hands. A wheel armature suspended from a magnet having just power enough to keep it from falling, and placed in vacuo is probably the nearest approach to such a machine ever attained by mortals. The pendulum hung on knife edges in vacuo will retain its motion nearly as long. Theoretically, if we can eliminate from any moving body all resistances, it would never cease moving and would become literally a perpetual motion, though not the thing sought. The motions of the tides, the rotation of the earth, and the motions of the heavenly bodies, will continue for ages, but of these there is not one of which an astronomer would dare to predict that it will never cease.

So far as we can see, there is no single motion in nature that can be called perpetual, though change is perpetual, and motion somewhere, either of molecules or masses, must, according to the conclusions of modern science, always exist. Such can be the only conclusion drawn from the doctrine of the "conservation of force," of which the great Faraday said that it is the highest physical law of which the human mind can form any conception.

The perpetual motion of which visionaries have dreamed, and for which enthusiasts have labored, is a machine that will, under ordinary circumstances, start itself and increase its motion till it reaches a maximum, overcoming the resistances of air and friction, and possessing a surplus of motion to spare for the impulsion of other machines not self-moving. That there may be no mistake, in terms, let us adopt the name of "self-mover" for this supposed desideratum. It is not a new term, but is the only one that does not mislead thought in the consideration of the subject. Of the term "perpetual motion" Prof. Nichol, in his "Physical Sciences," says:

"If this famous appellation had simply meant perpetuity or indestructibility of force, it would have stood for an important and undeniable truth. No force is lost in the universe; we never discern the loss, but only the conversion of force, e. g., when a machine is brought to a stand through friction, all that has occurred is—the force applied to move the machine has, through the resistance we call friction, been converted into a mechanical equivalent of heat; and this heat, by communication and radiation, is in existence playing its equivalent mechanical part. But this is not the common or practical conception attached to the term perpetual motion. It has ever signified as follows: A machine whose characteristic is that the initial or primary force shall be restored or replaced by the very movement it produces. Now, setting aside the fact that, in every machine of earthly materials, part of the initial force must ever be converted into heat and dissipated through effect of friction, it is clear that, were such a machine consummated, the effect would be not motion, but equilibrium or rest. A machine is a mere medium of connection between power at one end and effect at the other; and were these two equal, the machine would simply stand still. The negation of the possibility of perpetual motion may therefore be accepted as an axiom in mechanical science. Mr. Grove has recently shown, in a most ingenious essay read before the Royal Institution of London, that important uses may be made of this axiom as an aid in scientific research. He has illustrated, by many important instances, that, considered as a test, it might enable us to discern in any experiment to what degree of approximation we have obtained, from any given natural force, the total quantity of power it is capable of affording; and that it might also serve, on the discovery of any new phenomenon, to show up to what point that phenomenon might be put in relation with phenomena formerly known."

From what we have said it will be inferred that we believe a self-moving machine to be an impossibility; but while we entertain this view, we do not forget that many able minds have held an opposite opinion, and that it has been even claimed that in two instances such machines have been actually constructed. These instances will receive notice in their proper place hereafter. We do not, then, "sit in the seat of the scornful," in regard to those who have attempted to reach the goal which has by its delusive promises led many an unfortunate inventor on to his ruin. Nor will we dogmatically assert that our opinions are infallible. All we say is, that we believe those opinions founded on sound scientific principles, and that whoever tries to produce a self-mover is wasting his time, money, and powers to no purpose.

John Wilkins, the Bishop of Chester, who died in 1672, and who, during his life, wrote upon the subject, classes the means employed to reach the desired object under these heads:

1. By Chymical Extractions.
2. By Magnetical Virtues.
3. By the Natural Affection of Gravity.

He says:

"The discovery of this hath been attempted by Chymistry. Paracelsus and his followers have bragged, that by their separations and extractions they can make a little world which shall have the same perpetual motions with this microcosm, with the representation of all meteors, thunder, snow, rain, the courses of the sea in its ebbs and flows, and the like. But these miraculous promises would require as great a faith to believe them, as a power to perform them; and tho' they often talk of such great matters,— . . . yet we can never see them confirmed by any real experiment; and then, besides, every particular author in that art hath such a distinct language of his own (all of them being so full of allegories and affected obscurities), that 'tis very hard for any one (unless he be thoroughly versed amongst them) to find out what they mean, much more to try it.

"One of these ways (as I find it set down) is this: Mix five ounces of ☿ with an equal weight of ♃; grind them together with ten ounces of sublimate; dissolve them in a cellar upon some marble for the space of four days, till they become like oil olive; distil this with fire of chaff, or driving fire, and it will sublime into a dry substance; and so, by repeating of these dissolvings and distillings, there will be at length produced divers small atoms, which, being put into a glass well luted, and kept dry, will have a perpetual motion.

"I cannot say anything from experience against this; but methinks it does not seem very probable, because things that are forced up to such a vigorousness and activity as these ingredients seem to be by their frequent sublimings and distillings, are not likely to be of any duration. The more anything is stretched beyond its usual nature, the less does it last; violence and perpetuity being no companions. And then, besides, suppose it true, yet such a motion could not well be applied to any use, which will needs take much from the delight of it."

This example is enough, we think, to satisfy our readers of the absurd character of the attempts to obtain a self-mover by "chymical extractions," and though chemistry has advanced to the front rank of sciences since that time, any attempt to get a perpetual motion through its aid would be even more absurd to-day than in Wilkins' time, since it is, in a great measure, through the aid of this science that molecular physics has advanced to the knowledge of the "conservation of force."

The second class of means, viz., by "magnetic virtues," is exemplified by a device of which we give herewith an engraving (Fig. 1).

Of this, and similar attempts, our author says:

"But amongst all these kinds of inventions, that is most likely, wherein a loadstone is so disposed that it shall draw unto it on a reclined plane a bullet of steel, which steel, as it ascends near to the loadstone, may be contrived to fall down through some hole in the plane, and so to return unto the place from whence at first it began to move; and, being there, the loadstone will again attract it upwards till coming to this hole, it will fall down again; and so the motion shall be perpetual, as may be more easily conceivable by this figure:

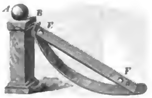

Fig. 1.

"Suppose the loadstone to be represented at A B, which, though it have not strength enough to attract the bullet, C, directly from the ground, yet may do it by the help of the plane, E F. Now, when the bullet is come to the top of this plane, its own gravity (which is supposed to exceed the strength of the loadstone) will make it fall into that hole at E; and the force it receives in this fall will carry it with such a violence unto the other end of this arch, that it will open the passage which is there made for it; and by its return will again shut it; so that the bullet (as at the first) is in the same place whence it was attracted, and, consequently, must move perpetually."

But however this invention may seem to be of such strong probability, yet there are sundry particulars which may prove it insufficient; for

"This bullet of steel must first be touched, and have its several poles, or else there can be little or no attraction of it. Suppose C in the steel to be answerable unto A in the stone, and to B; in the attraction, C D must always be directed answerable to A B, and so the motion will be more difficult; by reason there can be no rotation or turning round of the bullet, but it must slide up with the line, C D, answerable to the axis, A B.

"In its fall from E to G, which is motus elementaris, and proceeds from its gravity, there must needs be a rotation of it; and so 'tis odds but it happens wrong in the rise, the poles in the bullet being not in the same direction to those in the magnet; and if in this reflux it should so fall out, that D should be directed toward B, there should be rather a flight than an attraction, since those two ends do repel, and not draw one another.

"If the loadstone, A B, have so much strength, that it can attract the bullet in F, when it is not turned round, but does only slide upon the plane, whereas its own gravity would rowl it downwards; then it is evident the sphere of its activity and strength would be so increased when it approaches much nearer, that it would not need the assistance of the plane, but would draw it immediately to itself without that help; and so the bullet would not fall down through the hole, but ascend to the stone, and, consequently, cease its motion; for, if the loadstone be of force enough to draw the bullet on the plane, at the distance F B, then must the strength of it be sufficient to attract it immediately unto itself when it is so much nearer as E B. And if the gravity of the bullet be supposed so much to exceed the strength of the magnet, that it cannot draw it directly when it is so near, then will it not be able to attract the bullet up the plane, when it is so much farther off.

"So that none of all these magnetical experiments, which have been as yet discovered, are sufficient for the effecting of a perpetual motion, though these kind of qualities seem most conducible unto it; and perhaps, hereafter, it may be contrived from them."

From among many devices under the third class, we select the one shown in Fig. 2, whereby the desired motion is sought through the action of fluid weights:

"Where the figure, L M, at the bottom, does represent a wooden cylinder with helical cavities cut in it, which at A B is supposed to be covered over with tin plates, and three water wheels upon it, H I K; the lower cistern, which contains the water, being C D. Now, this cylinder being turned round, all the water which from the cistern ascends through it, will fall into the vessel at E, and from that vessel being conveyed upon the water wheel, H, shall consequently give a circular motion to the whole screw. Or, if this alone should be too weak for the turning of it, then the same water which falls from the wheel, H, being re-

* Reprinted from the Scientific American, 1870-71.

ceived into the other vessel, F, may from thence again descend on the wheel, I, by which means the force of it will be doubled. And if this be yet unsufficient, then may the water which falls on the second wheel, I, be received into the other vessel, G, and from thence again descend on the third wheel at K; and so for as many other wheels as the instrument is capable of. So that, besides the greater distance of these three streams from the center or axis by which they are made so much

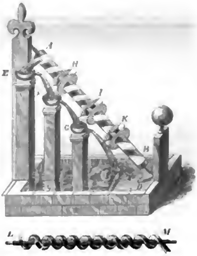

FIG. 2.

heavier, and besides that the fall of this outward water is forcible and violent, whereas the ascent of that within is natural—besides all this, there is thrice as much water to turn the screw as is carried up by it.

"But, on the other side, if all the water falling upon one wheel would be able to turn it round, then half of it would serve with two wheels, and the rest may be so disposed of in the fall as to serve unto some other useful delightful ends.

"When I first thought of this invention, I could scarce forbear, with Archimedes, to cry out eureka, eureka; it seeming so infallible a way for the effecting of a perpetual motion that nothing could be so much as probably objected against it; but, upon trial and experience, I find it altogether insufficient for any such purpose, and that for these two reasons:

"1. The water that ascends will not make any considerable stream in the fall.

"2. This stream, tho' multiplied, will not be of force enough to turn about the screw.

"1. The water ascends gently, and by intermissions; but it falls continually, and with force; each of the three vessels being supposed full at the first, that so the weight of the water in them might add the greater strength and swiftness to the streams that descend from them. Now, this swiftness of motion will cause so great a difference betwixt them that one of these little streams may spend more water in the fall than a stream six times bigger in the ascent, tho' we should suppose both of them to be continuate; how much more, then, when as the ascending water is vented by fits and intermissions, every circumvolution voiding so much as is contained in one helix; and, in this particular, one that is not versed in these kind of experiments may be easily deceived.

"But, secondly, tho' there were so great a disproportion, yet, notwithstanding, the force of these outward streams might well enough serve for the turning of the screw, if it were so that both its sides would equiponderate the water being in them (as Ubaldus hath affirmed). But now, upon farther examination, we shall find this assertion of his to be utterly against both reason and experience. And herein does consist the chief mistake of this contrivance; for the ascending side of the screw is made, by the water contained in it, so much heavier than the descending side, that these outward streams, thus applied, will not be of force enough to make them equiponderate, much less to move the whole."

In the library of the British Museum is an edition of "A very necessarie & profitable booke, concerning Nauigation, compiled in Latin by Joannes Taisnierus, a public professor in Rome, Ferraria, and other universities in Italie of the Mathematicalles, named a Treatise of Continuall Motions; translated into English by Richard Eden." It is a black letter quarto tract, printed by Richard Jugge, without date, consisting of eighty-two pages. The first part is "Of the Vertue of the Loadstone," and the second part is "Of continual motion by the said stone Magnes." It was reprinted in 1579. In his introductory remarks, he observes, in allusion to continual motion, that it is—

"The thing which to this day in manner from the beginning of the world, great philosophers with perpetual studie and great labour, have endeavoured to bring to effect, and desired end, hath nevertheless hitherto remayned eyther unknown or hydde, not without great damage & hyndrance of most expert mathematicians. . . .

"From the begynnyng of the worlde, in manner all naturall philosophers and mathematitians, with great expences and labour, have attempted to fynde out a continual motion or moovyng, yet unto this day have few or none atteyned to the true ende of their desyre. They have attempted to doo this with divers instrumentes & wheeles, & with quicksylver, not knowyng the vertue of this stone. Neyther can continual motion be founde by anye other meanes, than by the stone Magnes, in this manner. Make a holowe case of sylver, after the fashion of a concave glasse, outwardly laboured with curious art of gravyng, not onely for ornament, but also for lyghtnesse; the lyghter that it is, so much the more easyer shal it be mooved, neyther must it be so pearced through, that such as are ignorant of the hyd secrete, may easyly perceyve it. . . .

"It must have on the inner syde certayn little nayles & denticles or smal teeth of iron of one equal weyght, to be fastened on the border or margent, so that the one be no further distant from the other, then is the thycknesse of a beane or chick pease. The sayd wheele also must be in all partes of equall weyght, then fasten the exiltree in the myddest, upon the whiche the wheele may turne, the exiltree remaynyng utterly immoveable. To the whiche exiltree agayne shal be joyned a pynne of sylver, fastened to the same, & placed betweene the two cases in the hyghest parte, whereon place the stone Magnes. Beyng thus prepared let it be fyrste

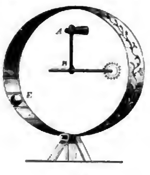

FIG. 3.

brought to a rounde fourme, then (as is sayd) let the poles be founde: then the poles untouched, the two contrarye sydes lying betweene the poles, must be fyled & pullyshed, & the stone brought in manner to the fourme of an egge, & somewhat narrower in those two sydes, lest the lower parte thereof shoulde occupie the inferior place, that it may touche the walles of the case lyke a little wheele. This done, place the stone upon the pynne, as a stone is fastened in a ryng, with such art, that the north pole may a little inclyne toward the denticles, to the ende that the vertue thereof woorke not directly his impression, but with a certayne inclination geve his influence upon the denticles of iron. Every denticle therefore shall come to the north pole, & when by force of the wheele it shal somewhat passe that pole, it shal come to the south part, whiche shal dryve it back agayne; whom then agayne the pole artike shall drawe as appeareth. And that the wheele may the sooner doo his office within the cases, inclose therein a litle calculus (that is a litle rounde stone or pellet of copper or sylver, of suche quantitie, that it may commodiously be receyved within any of the denticles; then when the wheeles shal be raysed up, the pellet or rounde weyght shal fal on the contrary parte. And whereas the motion of the wheele downwarde to the lowest part, is perpetuall, & the fal of the pellet, opposite or contrary, ever receyved within any two of the denticles, the motion shall be perpetuall, because the weyght of the wheele & pellet ever enclyneth to the centre of the earth & lowest place. Therefore when it shal permit the denticles to rest about the stone, then shal it well serve to the purpose. The myddle places within the denticles ought so artificially to be made belowe, that they may aptly receive the fallyng pellet or plommet, as the fygure above declareth. And briefly to have wrytten thus much of continual motion may suffice.

"Description of the Engraving, Fig 3.—A, the stone; B, the sylver pinne; E, calculus, a little rounde stone or small weyght."

Notwithstanding our author of the 15th century seems so satisfied with his invention, we find that two centuries later the world was still without the desired self-mover, for Jacob Leupold, in a work published at Leipsic in 1724, says:

"It still remains to find out this wonderful and undiscovered thing, which to the present time remains impossible both mathematically and mechanically, so far as we yet know. Great weight only increases friction, but there was a wheel or machine that did not weigh above forty pounds, and was nine feet diameter, which promised better results, yet failed like others, and so dissipated all hope of succeeding.

"Notwithstanding we hold that perpetual motion is not an impossibility, as has been shown to all the world by Councillor Orffyreus, and attested by the princely word of the Landgrave of Hesse Cassel, a prince himself well grounded in the science of mechanics, and who so minutely scrutinized and observed this wonderful motion, which was with him on trial during two months; all of which time he kept the machine in a sealed chamber.

"To all the seekers after perpetual motion the following remarks will be found most valuable:

"1. That they must endeavor to construct one of the simplest of machines; for the more material and workmanship, the less chance of durability. And if not found in such simple arrangement, it will be hid for ever.

"2. That it must be tried by experiment and not only on paper, for the friction and action can only be estimated by trial.

"3. That unless grounded in the fundamental principles of mechanics, no one should attempt the project, as he will only lose time and money. The thousands who fail of success yet learn something of mechanics, and that one pound cannot move more than one pound, but always arrives at an equilibrium."

In a work entitled "A History of the Manual Arts," we find the following:

"Archimedes, of Syracuse, the greatest mathematician and the rarest engineer that was in his time, invented a sphear and an artificial heaven, wherein he did represent the rotations and revolutions of the planets," and of which Claudian gives a poetic description—"that this machin did move of itself; it was an automaton, a self-moving device;" and further, "that these motions were driven and acted by certain spirits pent within;" also of another device of "a silver heaven sent by the Emperour Ferdinand for a present to Soliman the Grand Signior," with twelve men, and a book "that shewed the use of it, and how to order and keep it in perpetual motion." An account is next given of Cornelius van Drebble, a Dutchman, of Alcmar, engineer to King James in England:

"He presented the king with a rare instrument of perpetual motion, without the means of steel, springs, or weights; it was made in the form of a globe, in the hollow whereof were wheels of brass moving about, with two pointers on each side thereof, to proportion and show forth the times of dayes, moneths, and years, like a perpetual almanack."

The accompanying engraving, Fig. 4, is taken from a work by Robert Fludd, published in 1618.

It is a water wheel which is expected through a system of gearing to operate a chain pump, which pump should raise the water necessary to propel the wheel, and so on forever. It is probably unnecessary to inform our readers that this fallacious principle has been tried in various ways, and that there are occasionally yet to be found those so unskilled in mechanical science, and incapable of seeing the radical error of the device, as to waste their substance in a repetition of this time honored blunder. We have now in mind an instance in point, in which a man spent the accumulation of an industrious life in endeavoring through various makeshifts to get such a wheel to move, and who has brought poverty upon his declining years, through his absurd experiments. It was earnestly sought by his friends to convince him that nothing in falling could perform more work than that required to raise it to the point from which it is allowed to descend, but all such efforts proved vain, and our perpetual motion seeker would not desist till he had sunk his bottom dollar. "Perseverentia vincit omnia" was his reply to every argument and appeal, a motto which perhaps is true when applied to possibilities, and the failure of which in all the attempts to secure a self mover only strengthens the belief in the impossibility of the thing sought.

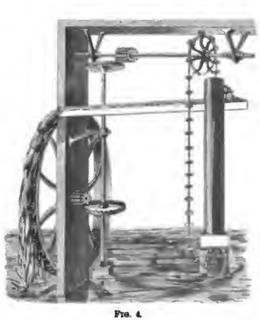

FIG. 4.

(To be continued.)

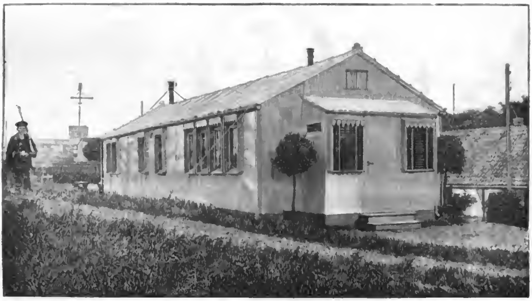
EMPEROR WILLIAM'S PAVILION ON HELIGOLAND.

FOR the time that the Emperor of Germany was to spend on Heligoland, at the occasion of the English Jubilee regatta, a pavilion was erected in the garden of the governor. It was constructed on the same pattern as the Döcker barracks, such as are supplied to the German, Austrian, Russian and other armies, the German navy and Red Cross societies. The usual dimensions for army use are 40×16 ft. The Emperor's barrack is some three feet longer. In its internal arrangements it differs from the others only by a slightly modified distribution of the rooms and by richer wall decorations. The whole, too, is finished in more elegant style. Besides a drawing room of 18 ft. 6 in.×16 ft. 3 in., the pavilion contains a bed room 16 ft. 3 in. square, and a bath room 16 ft. 3 in.×9 ft. 9 in., a servants' room 13 ft.×6 ft. 6 in., and a hall, 6 ft. 6 in.×3 ft. 3 in. In front of the drawing room there is an ante-chamber attached to the main part of the pavilion. Its dimensions are 9 ft. 9 in.×3 ft. 3 in. The floor is made up of 24 boxes, which serve to pack the walls, etc., for transport. When empty, they are hooked into one another by a peculiar system of connections, and they then form a strong, stable foundation for the barrack. On them the walls are erected, and they support the pavilion. All parts of the building are connected and held together by ingenious bolts.

Notwithstanding the strong wind of Heligoland, the pavilion was built up in eight hours. It stands on a small hill in the beautiful garden of the governor, with a charming view from the gable, over the sands.

The interior is simple, but elegant. The floors are covered, some with carpet, others with linoleum, and light hangings, in harmony with the furniture of the room, adorn the windows. A stove supplied by the firm Junkers and Ruh, of Karlsruhe, stands in the drawing room. The bath and stove were supplied by Joseph Junk, of Berlin, while the decorative painting was done by Lange, the hanging of the curtains by Kämpfer, both of Berlin.

For our illustration we are indebted to Illustrirte Zeitung.



EMPEROR WILLIAM'S PAVILION, HELIGOLAND.

THE PADDLE STEAMER WALTON BELLE.

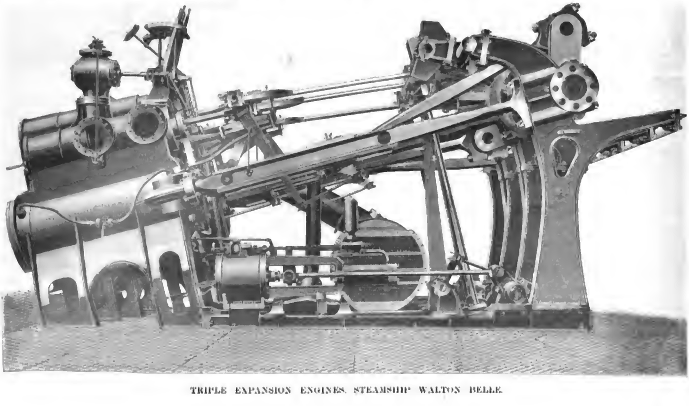
A VALUABLE addition to the well known pleasure fleet of the Belle Steamers Company, Limited, has just been contributed from the Dumbarton yard of Messrs. William Denny & Brothers, the builders of the four other steamers owned by the company. This vessel—the Walton Belle—having first run her official trial satisfactorily on the Firth of Clyde was recently taken upon an opening trip from Fresh Wharf to the Mouse Light and back. Messrs. Denny's first contribution to the fleet of the Belle Steamers Company was the Clacton Belle of 458 tons, built in 1890. Then followed the Woolwich Belle of 298 tons, in 1891; the London Belle of 738 tons, in 1893; the Southend Belle of 570 tons, in 1896; and now the Walton Belle of 470 tons.

Colonel John M. Denny, M.P., humorously remarked on the occasion of the recent trip to the Mouse and back: "This boat is not so big as the larger ones, but she is technically and scientifically the biggest success in paddle propulsion we have ever built." In view of Messrs. Denny's performances with their Belgian, Stranraer, and Arran paddle steamers, this is saying a very great deal indeed for the efficiency of the Walton Belle. This vessel measures 230 ft. long by 26 ft. broad, and 10½ ft. moulded depth, and has a promenade deck 104 ft. long. She is primarily intended for a new service between Clacton and Yarmouth just opened by her owners in connection with their trade from London Bridge.

The steamers of the Belle Company have done a great deal toward attracting Londoners from the railway to the sea as a way of taking a summer day excursion. Already the Thames enjoys almost as great facilities in this respect as the Clyde itself, which is the birthplace of the coast excursion paddle steamer. With five millions of possible customers so close at hand, there seems no reason why this enterprise should not only prove a boon to the population, but a source of profit to the companies which have developed it. It is gratifying to learn from Mr. Peter Denny that the owners of this fleet of vessels, which have navigated the Thames and the Essex coast for six summers continuously, carrying many thousands of passengers in that time, have never lost a single life.

This success is no doubt largely, and, indeed, principally, due to the thoroughness with which the owners and their staff have conducted their operations, both in the efficiency of the vessels they have acquired and in the care with which they have been navigated. The hull of the Walton Belle is divided into nine watertight compartments, which subdivision renders her practically safe against foundering under any conceivable circumstance.

The accommodation for passengers is provided in the usual handsome and luxurious style peculiar to the fleet. The principal apartment is a "social hall," the framing of which is of polished oak and sycamore, with panels of lincrusta, the ceiling being painted and gilded to harmonize, and the entire apartment brightly lighted



TRIPLE EXPANSION ENGINES, STEAMSHIP WALTON BELLE.

by means of large windows. The sofas are upholstered in blue figured velvet, and arranged in bays, while the windows are curtained in blue and gold tapestry, the general appearance being that of a homelike drawing room.

The first class dining saloon, which is situated on the lower deck, has seating accommodation for one hundred persons at a time; the framing of this apartment is in yellow pine artistically painted, while the upholstering is in figured velvet harmonizing in color with the general decorative design of the saloon. As the total number of passengers that may be carried by the steamer is 1,500, another dining saloon is provided at the forward part of the vessel to supplement the main saloon when she is crowded. A saloon is also placed forward for the convenience of second class passengers. In addition there is a handsome boudoir for ladies, besides private cabins and private dining accommodation. The promenade deck, already alluded to, is fitted with comfortable seats, which are designed so as to serve as life rafts in an emergency. An installation of electric lighting is provided, and an elaborate system of ventilation. For handiness in navigating the upper Thames a bow rudder and suitable steering gear are fitted, while powerful steam steering gear is provided for the main rudder and controlled from the flying bridge.

The Walton Belle is propelled by a set of direct action, triple expansion, diagonal, surface condensing engines, with cylinders 20½ in., 30 in. and 43 in. and a 60 in. stroke. In order to secure both lightness and strength, cast and ingot steel, to the exclusion of cast and wrought iron, have been used wherever practicable in the machinery. The engine has three cranks, which arrangement tends to steadiness of motion. The high pressure and intermediate cylinders are fitted with piston valves and the low pressure cylinder with a double ported slide valve, all being worked by Brock's valve gear, which insures uniformity of lead at all grades of expansion. The reversing is effected by Brown's combined steam and hand gear, all the levers being brought to the starting platform.

Steam is supplied from a multitubular boiler, working at a steam pressure of 160 pounds, and constructed in accordance with the Board of Trade requirements. Forced draught arrangements are fitted in a closed stokehold, the air being supplied by a fan driven from a Bumstead engine. Denny & Company's patent spark arrester is fitted in the funnel.

The trial runs between the Cloch and Cumbrae lights on the Firth of Clyde gave a mean speed of 17·09 knots, as compared with the contract requirement of 16½ knots.

For our engraving and the foregoing particulars we are indebted to The Engineer.

LEGS OF RACING CYCLISTS.

Our illustrations show the front and rear views respectively of the legs of some well known professional cyclists. For years sporting journals have debated the question as to what is the form of musculature most desirable for a cyclist's legs, without arriving at any very definite conclusion. There is also a difference of opinion as to what part of the body has to bear the greatest strain. According to some physicians, the heart is brought into excessive action, while others hold just the contrary, that the work is rendered easier for that organ, by the task required of the other muscles, mainly those of the thigh, the cardiac spasms resulting more easily owing to the impulse given to the circulation. These advocates of cycling, moreover, state that, while other athletic exercises requiring great efforts and muscular work produce on the one hand an accumulation of carbonic acid gas, and on the other, through the frequent closing of the glottis, shortness of breath, in cycling there is no accumulation of carbon dioxide, the product of the combustion caused by the muscular work. The movement being distributed evenly over the body, the work is comparatively small, while the blood is freely supplied with oxygen by the frequent inhalations.

These details are given by Dr. Jennings. But the remarks surely do not quite apply in the case of prolonged or very rapid wheeling.

However, let us return to the subject of our illustrations. Photographs were taken of the limbs of these professionals, to establish whether they showed any analogous development. One glance at the cuts will convince the reader that such is not the case. Beside the fine anatomy of Jaap Eden, Lamberjack, for instance, shows no very remarkable build. Many noncyclists have as good thighs as Fournier, Gougoltz and Fischer. As for Huret, a stayer, strayed into the number of these sprinters, it is not his legs that distinguish him from the rest. One characteristic common to all is the abnormal development of the crural biceps and triceps, noticeable particularly in Jaap Eden. In him it becomes almost a professional deformity.

It is a pity that this reproduction in black and white cannot give fully the tint of the limbs. They are all spotted and scarred; on Lamberjack we notice a plaster at the knee. These are trophies from occasional collisions, such as occur on all racing tracks.

There seems to be no precise indication from which we can judge what is the ideal cyclist's leg. Medical men express no opinion on the question. Choppy Warburton, the famous trainer of Linton, Michael and Champion, alone has the confidence to make any assertion with regard to that question.

The professional cyclist, he says, must be an athlete. Any man who has had success in any branch of sports which requires endurance will also have triumphs on the track. Thus Eden was formerly a great skater. As for his bodily conformation, the cyclist should be built somewhat like a dog: a wide chest, in which the lungs can work freely; the lower limbs should present long, powerful levers, as in a greyhound. Zimmermann, the great American champion, had remarkably long thighs.

So much for the opinion of professionals. Our cycling readers may make their own observations from the two cuts which we borrow from L'Illustration, and form their own opinion accordingly. We will say no more, but leave them to study these assorted human limbs.

BRASS FACING ZINC HALF TONES AND THE METAL MOUNTING OF SUCH BLOCKS.

By E. L. Ectro.

As the unprotected surface of a zinc half tone is very liable to damage, many remedies have from time to time been suggested and tried. It has been found that a thin coating of brass has proved of great service in this direction, and an easy and simple way of depositing this alloy is here given.

Of the merits or otherwise of the hot or cold process it is not necessary to say much. Each bath has its adherents, and as both a hot and a cold bath formula is given in this paper, the worker can choose that which suits him best, as, with the exception of making up the solutions, the working is practically the same in both instances.

COLD BATH FORMULA.

Zinc carbonate	10	parts.
Copper carbonate	10	"
Soda carbonate	20	"
Soda bisulphite	20	"
Potassium cyanide	20	"
Arsenious acid (white arsenic)	1	"
Water	1,000	"

To make up the solution proceed as follows: Take twelve parts of sulphate of copper and twelve parts sulphate of zinc and dissolve them in water, then add carbonate of soda, already dissolved, to the solution. This precipitates the copper and zinc in the form of carbonates, a greenish colored powder. Allow the precipitate to settle, and pour off the supernatant liquor. Wash the precipitate, and then mix it with the carbonate and bisulphite of soda in 900 parts water. Next dissolve the cyanide and arsenic in the remaining 100 parts water and pour this into the first solution. The bath is now ready for use.

HOT BATH FORMULA.

Copper acetate	14	parts.
Zinc chloride	14	"
Potassium cyanide	30	"
Soda bisulphite	28	"
Ammonia	16	"
Water	1,000	"

Dissolve the cyanide and bisulphite in 800 parts water and add to it the other ingredients dissolved in the remaining 200 parts water. This solution is used at a temperature of about 120 deg. Fah. The vessel for containing this solution may be of iron lined with brass, and the temperature maintained by hot water, gas, fire, or steam. The cold bath can be used in an ordinary earthenware vessel, or, if the work runs large, a wooden tank lined with guttapercha will answer admirably.

The anodes should be of good stout brass. They should occasionally be removed from the solution to be cleaned, and the connections generally seen to. Care should also be taken to prevent any of the solution getting upon the hands or clothes; if such should happen, it should be immediately washed off with water.

A pair of Bunsen cells in series will be required to

deposit the metal. The cells and the method of connecting them were fully described in the issue for October, 1896, but for those readers who have mislaid that number a few brief notes are here given. The Bunsen cell consists of an outer earthenware jar containing a 10 per cent. solution of sulphuric acid. Into this a zinc cylinder amalgamated with mercury is placed. A porous pot with a block of carbon in it is filled with pure commercial nitric acid, and then placed within the cylinder of zinc, and the battery is complete.—The Process Photogram.

RAPID PROCESSES OF UNLOADING ARTILLERY MATERIAL FROM CARS.

The ordnance department is just now studying some rapid processes of unloading a battery from a train upon an open track and with its own resources. It is possible that, during the course of a war, a battery of artillery may have to be taken off a train in the open country without the aid of any of the arrangements and accessories that are found at stations for assisting in such an operation. The destruction of a track, the occupation of a station by the enemy and an unexpected attack are so many circumstances under which the artillery would have to be unloaded from the train under such conditions; so, in recent times, much attention has been paid to this question. Several processes have been studied and put to the test in France as well as in other countries. The one that appears destined to be adopted by us is that proposed by Capt. Barthelemy.

The photographs herewith reproduced represent different phases of the unloading of a battery by this method. These photographs were taken during the course of experiments made at Fontainebleau by one of the flying batteries of the seventh division of cavalry.

Capt. Barthelemy's system is based upon the following principles: (1) The utilization of the hind ladder of the forage wagon or of the artillery wagon separated from its forecarriage as an inclined plane for unloading the horses; (2) the descent of the fore and hind carriages of each wagon separately by manual labor, and, when either of them is about to touch the ground, the receiving of its hubs in some kind of support that will allow the wheels to come into contact with the earth without shock.

The unloading of the wagons of a battery will, of course, begin with the one that is to serve as a descent for the horses.

The best of the vehicles to use for this purpose is the forage wagon, which, on account of its length, gives a very gentle slope.

The artillery wagon, which gives a steeper slope, is used only in case of the absence of the forage wagon. After the wagon that is to be used as an inclined plane has been taken off the car, its fore carriage is removed, and there is thus obtained a very convenient gangway, so to speak, that just reaches the level of the floor of the wagons. Upon the floor of the wagon there is spread straw and sand, in order to render its surface less slippery.

Fig. 1 represents an unloading of horses effected by means of a battery wagon. The party that made the experiment during which our photographs were taken had no forage wagon at its disposal.

As the hind carriage of an artillery wagon is connected with the fore carriage by means of a short pole, it is the latter that rests upon the earth when the two parts are detached. The men seen at the two sides of the wagon are there to prevent any motion during the descent of the horses and to keep its upper part in close contact with the floor of the car. Further to the left is seen a man with a shovel ready to throw sand upon the floor as soon as the horse has been disembarked.

Fig. 3 represents the unloading of a fore carriage. By means of ropes possessed by the battery, the wheels have been tied, so that it will be impossible for them to revolve.

Two men placed upon the other side of the truck hold back the descending wheels by means of a rope. This rope makes one revolution around the axle of the truck, and this gives the two men considerable of a purchase. Ten other men cause the wagon to advance while holding it.

The accessory supports mentioned above have been prepared in advance and are as follows: With a forage rope there is formed a sort of sling which is placed upon the point of one of the large pickets that are carried under the artillery wagons and that are used for attaching horses to by means of ropes during a bivouac.

As soon as the axle of the fore or hind carriage that is descending reaches a distance from the earth a little greater than the height of the picket supports, one of the latter is fixed by its sling to each axle. The axle continuing to descend, the supports touch the earth. Then, instead of continuing to descend vertically, it pivots around the two points of the supports that rest upon the ground, and the tires of the wheels touch the latter without any shock.

The descent of the hind carriage of a wagon is effected in the same manner, with the difference that, as soon as it is possible, it is connected with the fore carriage that has already been unloaded.

Fig. 4 shows the descent of a hind carriage. The picket supports are here already fixed to the hubs. A gunner standing on each side holds each of the supports exactly vertical, in order that no sliding may occur when the carriage pivots around the bearing point of the supports.

All the wagons of the battery except the ammunition ones are unloaded as we have just explained. As the fore and hind carriages of the ammunition wagons cannot be separated, the latter have to be unloaded in their entirety.

In order to perform this operation everything is taken out of the wagon, and then its fore carriage is made to pass over the edge of the truck, while a sufficient number of men to balance it get on behind, so as to allow the front wheels to touch the ground without shock. The descent is effected entirely by manual power. Fig. 2 clearly shows the mechanism of this operation.

The unloading whose phases are here reproduced, and which included that of eighteen wagons and two hundred horses, took about two hours.—La Nature.

Fig. 2.—METHOD OF LETTING DOWN AN AMMUNITION WAGON.

WIND PRESSURES ON HIGH BUILDINGS.*

We have been particularly requested to lay before our readers an abstract of the long, but very valuable, paper on wind pressure prepared by Mr. Julius Baier, Assoc. Mem. A. S. C. E., but it has seemed best to us to print the following copious extracts from his paper rather than a briefer abstract:

The storm of May 27, 1896, entered St. Louis from the west, progressed eastwardly through the city at some distance south of the central business section, crossed the Mississippi River and continued in a northeasterly direction through East St. Louis. . . .

The anemometer record shows the passage of 13 miles of wind in about 12 minutes; of this, a little over 8½ miles passed in five minutes, a rate of about 80 miles an hour observed, giving, when properly corrected, an actual velocity of about 62 miles per hour. The general direction was toward the south, into the storm center. . . .

A general inspection of the buildings brings out the following average characteristic features. The extreme force of the wind was generally confined to upper stories and roofs. The intensity of this force must have been extremely variable, not only as exerted on adjacent properties, but on a single building. There was very general evidence of the destructive force being exerted from the inside.

The total number of buildings destroyed or seriously damaged by the storm in the city of St. Louis, as shown by the records in the assessors' office, is 7,263. Of these, 321 were totally wrecked. The number of houses slightly damaged that can be repaired at an average cost of $75 is 1,249, making a total of 8,515. . . .

The general maximum destruction covers an area from 4,000 feet to 6,000 feet wide and nearly three miles long, lying immediately south of the central part of the city in St. Louis and extending across the river into East St. Louis. . . .

Throughout the path of the storm the buildings and wreckage show evidence of extreme and sudden variations in the intensity of the wind pressure. A striking example of this is a little pavilion left standing in Lafayette Park on a slight elevation above the general level, at a point where the broken and uprooted trees show the full force of the storm. A straw thatched roof held in a light wire netting and perched on six uprights planted in the earth, and stiffened by a few rustic braces, would seem a most inviting mark for the wind, but except for some damage due to the falling limbs of adjacent trees, it stands uninjured. . . .

Any formula expressing the relation between the pressure and velocity of the wind must be based on the assumption that the air flows in a uniform current. All experiments in the open air show that the actual conditions are far different, and the great diversity in the observed results is due largely to the continued and rapid fluctuations in the velocity of the winds. . . .

As a result of these observations Professor Langley reaches the conclusion that "the wind is not even an approximately uniform moving mass of air, but consists of a succession of very brief pulsations of varying amplitude, and that, relatively to the mean movement of the wind, these are of varying directions."

Regarding the direct effect of wind pressure on buildings, some suggestive results were obtained by Professor Kernot* with an apparatus devised to determine the relative pressures of the wind on flat plates, cubes, cylinders and other forms similar to those employed in ordinary construction. A steady jet of air 10 by 12 inches in cross section was directed against small models supported on a very delicately arranged carriage running on an accurately leveled surface plate, the force exerted being measured by a delicate spring balance. From a large number of experiments made with this apparatus he found that the pressure on sloping roofs agreed with the results of theory only when the air could blow freely underneath. With the model of a roof placed on a wall, as in an ordinary building, the air was deflected upward and greatly reduced the pressure on the roof; the effect was more marked when a parapet was used. In the case of a roof of 30° pitch, with a parapet 0·16 the height of the roof, the pressure was actually reversed, the roof having a slight tendency to lift. Experiments were tried as to the effect of the wind blowing in at the open end of a building having the sides and other end completely closed, and it was found that there was an internal pressure, tending to lift the roof and force out the sides,

* Extracts from a paper by Julius Baier, Assoc. M. Am. Soc. C. E., read before the American Society of Civil Engineers, and published in the Journal of that Society.

* Engineering Record, February 10, 1894.

which was equal to the pressure of the wind on the exposed end. When a plane surface parallel to the wind was brought nearly into contact with the cylinder, the pressure on the latter was increased nearly 20 per cent, owing to the lateral escape of the air around the cylinder being checked, showing that a tower or chimney will be subjected to a much greater pressure if there is a building nearly touching it on one side. The variations of pressure caused by the proximity of other surfaces were very marked; each surface appeared to affect the pressure on the other surfaces to a distance in front equal to its own breadth, and in the rear equal to several times this distance. Behind flat surfaces eddies were found to exist which caused other surfaces placed behind them to be urged forward with considerable force.

The existence of a suction on the leeward side of surfaces or bodies exposed to the wind has been generally recognized, but the experiments of Mr. Irminger,* a Danish engineer, made to determine the amount of such suctions, shows it to be present to an unexpected extent. . . .

The most interesting result was that found for a roof sloping at an angle of 45°. The pressure on the windward side was a maximum at the eaves, and became zero near the top, changing to a suction at the ridge. The effect on the leeward side was a uniform suction. Taking the normal pressure on a plane of the same dimensions as equal to p, the proportional effect on the windward side was found to be a pressure of 0·11 p, and on the leeward side a suction of 0·36 p. The resultant effect on the total roof was a force 3½ times as large as the pressure on the windward side alone, and was inclined upward, exerting a strong lifting action. In another experiment made with the model of a building covered by a dome, the resultant of the pressure and suction upon the dome was found to act vertically upward.

The results of these experiments show that the wind acts in a direction quite different from that generally assumed and usually provided for in the designing of bridges, roofs and buildings. The evidences at St. Louis confirm this conclusion. . . .

Much of the destruction in St. Louis was undoubtedly caused by an intensity of wind pressure that it would be neither possible nor expedient to provide against in ordinary structures, but much of it was also due to weak construction. A general observance of the ordinary requirements for good building work would largely decrease the damage due to such storms. The great amount of explosive action was largely due to the comparative weakness of ordinary walls against pressure exerted from the inside of buildings. A more efficient anchorage of the walls might limit this explosive action to the windows. In numerous instances the windows were blown in on the windward side, while the entire wall was blown out on the leeward side. Brick walls are materially stronger if well bonded with the vertical joints filled with mortar, and a wall laid in cement will undoubtedly withstand a greater lateral force than one laid in lime mortar. It is worth noting that the walls of the buildings of the Union Depot Railway plant left standing were laid in cement, while the older buildings, which were entirely wrecked, had had walls laid with lime mortar. The great damage done to the churches calls attention to the great exposure of the steep and lofty roofs supported on high and comparatively thin and unbraced walls. Heavier buttresses or independent steel column supports, with bracing for the roof trusses, would materially increase the safety of such structures. In general, the buildings with large areas of unbraced walls have suffered most. . . .

The periodic prevalence of these storms, emphasized by the recent calamity in St. Louis, by the destruction in Louisville in 1890, and by a similar storm in Little Rock in 1894, and in Kansas City in 1886, gives a somewhat broader public interest to this question, and appears to call for its serious consideration. The evidence of the work of the wind in St. Louis suggests as an immediate answer to the question that it will depend largely upon the nature of the metal framework in the building. . . .

The metal framework of a building is somewhat generally called the "skeleton" and sometimes "cage." If both of these terms are to be retained in this special sense, a convenient distinction can be made by some restriction in their use suggested by the words themselves.

Skeleton is a term clearly descriptive of that type of construction to which it was first applied, a simple framework of columns and beams whose efficiency is dependent largely on the existence of exterior walls and partitions which brace the building, and hold the framework in position, just as the utility of the human skeleton is dependent upon the covering of sinews and muscles that hold the component parts together. On the other hand, the light framework of an ordinary wire cage bound into one compact unit is suggestive of an inherent strength and elastic resistance that renders any covering an incident rather than a necessity. Cage is a term peculiarly descriptive of that type of construction represented by the most advanced and approved practice, a framework of columns and beams, spliced at the joints, riveted at the connections, stiffened by an efficient bracing of rods, portals and gussets that make it independently safe against any external force, leaving the thin and light exterior walls with no duty except that of providing protection and ornamentation for the building.

The effect of an extreme wind pressure on a high office building with curtain walls must depend largely on the extent to which the frame of that building partakes of the nature of the skeleton type or the cage type of construction.

The possible work of destruction of a tornado may appear more clearly if, as Ferrel suggests, the column of rapidly revolving air is likened to a tall flue, with heated and rarefied air in its interior. If the access of air is cut off from the lower central part by the shell of gyrating air extending down to the surface, the lateral currents and ascending currents in the interior will be of no violence, but with a somewhat free access of air below into the rarefied interior, on account of a decrease by friction of the gyratory velocity near the surface, the inrush of lateral air currents becomes extremely violent and the velocity of the uprush of air in the interior becomes enormous. In the former case, the destruction is mainly due to the excessively high gyratory velocities; the destruction is complete, but the path narrow. It is the condition that may prevail in open country with but few objects to destroy the energy of the tornado. In the latter case the destruction is largely due to the violent lateral inrushing currents. The path is wider, and the force not so extreme. It is the condition which must prevail in any compactly built city, owing to the great friction of the air arising from the irregularities due to the many buildings.

The first high isolated building encountered will feel the full force of the gyratory velocity, but the resistance of the building destroys this velocity, and the work of destruction wrought on that building must represent an equivalent diminution of energy in the lower section of the tornado, which can only be renewed by its further unobstructed progress during such appreciable time as is necessary to restore the gyratory velocity. A succession of high buildings will prevent such recovery of velocity.

The destructive power of a tornado on massive building work due to these excessively high velocities is therefore soon exhausted, but the wind pressures due to the violent currents rushing in from all sides are only intensified thereby.

If a tornado storm with a well developed whirl should pass through the section of any city containing very high buildings, the general level of the top of the lower buildings becomes equivalent to the ground surface, and it seems fair to assume as the result the same general action that has been found near the surface, modified or intensified in its irregularity according to the degree of uniformity in the general height of the majority of the buildings. There may be the extreme pressures due to the gyratory velocity of the tornado proper exerted over a limited area and for a very limited time. There will be a far wider zone of lateral inrushing winds at high velocities lasting throughout the progress of the tornado and attended by the additional complications that may arise due to the concentration of air currents in the deep valleys formed by the streets between the buildings. The probable result would be an extremely variable and intense action of the wind about the tops of the lower buildings, the same action concentrated locally at about that level on the higher buildings, accompanied with a general severe pressure over the entire exposed area of the latter, this latter pressure probably being a maximum near the top or at least some distance above the general level where the friction is not so great.

A characteristic feature of the St. Louis tornado, and one which, judging from records and published views, is also common to other tornadoes and violent hurricanes, is the general destruction of the ordinary brick and stone walls. Regardless of the sequence in which they may explode outward or are blown inward, and of a possible difference of opinion as to whether the explosion is due to a plenum, a vacuum or to a suction, the essential fact remains that the walls do very generally fall.

Assuming a similar action of the wind, the buildings of an average height will probably have the walls at the top or exposed corners destroyed, or, if particularly weak, may be shaken down. The buildings above the average height would be very liable to have part of the walls at any level blown in or taken out. An office building with the curtain walls of one or more stories removed would support the remaining enveloped superstructure precisely in the manner of the grain elevator before it was struck by the storm.

If now the building is of the pure skeleton type, it will have only the elements of stability that existed in the case of the elevator—its weight—above the floor in question, and possibly some additional bracing of a more or less uncertain value, and under the action of even such pressure as may exist at some distance from the vortex of the tornado, it will fail, just as the elevator failed; it will topple over and fall to one side or toward one corner on the floor below. Instead, however, of landing on a massive stone foundation, the thousands of tons of weight of the three, four or six stories, as the case may be, of the upper section of the building will fall with a crushing force, concentrated on the leeward side, on the section below. The heavy oak girders under the leeward edge of the elevator were mashed into a bundle of splinters, while the windward edge was held some distance above the foundation. As the striking force of a freely falling body is equal to the product of its weight multiplied by the distance through which it falls—about 12 feet in the case of an office building falling one story—the resulting pressure on some of the columns may easily be ten to twenty times the load they were designed to carry and several

FIG. 3.—REMOVAL OF A FORE CARRIAGE FROM A PLATFORM CAR.

FIG. 4.—REMOVAL OF A HIND CARRIAGE FROM A PLATFORM CAR.

* American Architect, September 14, 1896.

times their ultimate strength; the result must be a collapse of part or all of the lower section, with a possible toppling over of the upper section to one side into the street or onto a lower adjacent building.

If the building is of the cage type, it will stand safely under a wind pressure that will destroy the skeleton building. While the failure of the walls at any story may reduce the rigidity somewhat, it cannot affect the strength of a framework designed without placing any dependence on the covering. Such a framework will readily carry the lateral stresses from the upper section to the section below.

If the pressure should reach a destructive intensity, the exact line of yielding of a cage frame is not so clearly defined. The tendency to lateral displacement will be a maximum at some one story, depending on the distribution and cumulative effect of the wind pressure, aided possibly by the weakening due to localized failure of walls or partitions. As the frame is of a gradually varying strength from the top down, the distortion can hardly be confined to one level, but would probably involve the members of the adjacent stories, the effect being a general racking or leaning of the building. With strains near the ultimate strength, the failure at some point may concentrate a distortion at that level, and the upper section of the building may be pushed to one side and ultimately settle down on the floor below.

The essential difference lies in the fact that a wind of sufficient force and duration to push the upper section of a building to one side a distance about equal to the width of a column may cause total destruction in a skeleton building, while a cage under the same circumstances may suffer only a local damage that can possibly be repaired at a comparatively small cost. In a skeleton building, the instant the columns are pushed beyond the critical or balancing point, the weight is reversed in its action from an element of safety to an almost unresisted element of destruction. With a cage type of construction the weight of the building after some displacement has taken place also acts with the wind as a destructive agent, but not unresisted. The work that must be done in the necessary bending, twisting, and general distortion and breaking of the metal in the columns and beams must largely absorb the energy of the falling mass and have the effect of letting it settle down on springs. The local peculiarities of the building, the unequal distribution of the wind pressure, and the changing direction of the wind, make it more than probable that such failure will not be symmetrical, but will have a torsional effect on the upper section of the building.

However difficult it is to foresee the many possibilities, it is safe to assume that in one way or another the framework will hang together sufficiently to prevent any considerable part of the building from falling down bodily onto streets or buildings below. Even under the most extreme conditions it is difficult to conceive how such a building, or a large part of it, can entirely collapse. The general destruction of windows and walls will greatly relieve the wind pressure; the frame, partly bent, twisted and distorted, must still hold together. The chances are that most of the occupants will escape alive and many uninjured. The most striking feature of the St. Louis tornado is the countless number of hairbreadth escapes and the very small number of people killed inside of houses unless by the entire collapse of the structures; incredible as it may seem, under such extreme conditions, the fatalities attending only local failure of a building are comparatively few.

The effect of a destructive wind pressure on any high building with curtain walls may be assumed to approach that outlined above in proportion as its framework partakes of the nature of a skeleton or cage type of construction, using these terms in the restricted sense indicated in this paper.

The destructive effect of the total collapse of buildings has been too frequently noted to require further mention. The method of failure of the grain elevator, taken in connection with the view of the wreck of the skeleton framework, indicates what might happen to a high building of the pure skeleton type if brought to the point of failure. The assumed action of the cage type of building is dependent on an efficiency in general design, and particularly in the detailing of connections, which can be readily attained if the necessity for it is recognized. In the absence of any definite tests of full sized typical details used in the structural work of buildings, the action of the metal under extreme distortion must be estimated from the results shown by sample specimens, verified by occasional opportunities to notice its behavior under accidental tests of great severity that may be caused by collisions or derailments on or near bridges and viaducts. The riveted joints, mentioned earlier in the paper, show what may be expected in details involving similar principles of design.

The possibility of a high office building being actually subjected to a destructive wind pressure has often been considered, largely in the light of a theory. The St. Louis tornado passed within less than a mile of the office buildings in that city. Fortunately it made no test of the buildings, but it has left some definite evidence of the possible force of the wind and of the action of this force on the materials of construction. While it raises anew the question as to the amount of wind force which should be provided for in designing high buildings, it raises with more emphasis the question as to the method of providing for this force after its amount has been assumed. Any dependence placed on curtain walls and partitions for lateral strength is open to very grave question. The rigidity imparted to a building by the simultaneous action of the total mass of material under ordinary conditions is no indication of the ultimate strength that may be developed at a critical moment, and the very general failure of the walls under extreme wind pressure further destroys any certainty of such assistance as might be otherwise relied upon. The elements of safety against wind force, exclusive of the strength that may come from the walls and partitions where they exist, are the stability due to weight alone, stability due to the strength and stiffness of the frame, and, when the force is a sudden one, the inertia of the mass resisting motion.

It may be of interest to estimate just how sudden and how short lived the force must be to justify placing any dependence on the inertia of the structure for safety. The force required to set in motion and move over a given distance any mass, otherwise balanced, is capable of exact computation if the time allowed for such motion is known. The equation is derived from the law for falling bodies and is $F = \frac{2\,w\,d}{g\,t^2}$, where F is the total force, w the weight moved in pounds, d the distance moved over in feet, t the time in seconds, and g is 32·2.

The following table, computed from this formula, gives the force required to overcome the inertia of a ton of 2,000 pounds and move it varying distances in times varying from one second to thirty seconds.

FORCE PER TON REQUIRED TO OVERCOME THE INERTIA OF AND MOVE ANY GIVEN MASS.

Time in Seconds.	Distance Moved.									
	1 in.	3 in.	6 in.	1 ft.	2 ft.	4 ft.	6 ft.	8 ft.	10 ft.	16·1 ft.
1	10·3	31	62	124·22	248	497	745	994	1,242	2,000
2	2·6	7·7	15·5	31	62	124	186	248	310	500
3	1·15	3·4	6·9	13·8	27	55	83	110	138	222
4	0·64	1·94	3·9	7·7	15·5	31	46	62	77	125
5	0·41	1·24	2·4	4·9	9·9	19·8	30	40	49	80
6	0·28	0·86	1·72	3·4	6·9	13·8	20·7	28	34·5	55
8	0·16	0·48	0·97	1·94	3·8	7·7	11·6	15·5	19·4	31
10	0·10	0·31	0·62	1·24	2·4	4·9	7·4	9·9	12·4	20
15	0·046	0·14	0·27	0·55	1·10	2·21	3·3	4·4	5·5	8·9
20	0·026	0·078	0·155	0·31	0·62	1·24	1·86	2·5	3·11	5·0
30	0·012	0·035	0·069	0·138	0·28	0·55	0·83	1·10	1·38	2·22

Assuming, as an illustration, the weight of a ton suspended as a pendulum by a very long cord; then to swing it one foot in one second will require a force of 124·2 pounds, while the mere pressure of 1¼ pounds will accomplish the same result if the time allowed is 10 seconds, or about the average duration of a gust of wind in Prof. Langley's experiments. Applying the figures in the table to the case of a narrow building, say 32 feet wide, and assuming the upper section 100 feet high by 100 feet long, having thus an exposed area of 10,000 square feet to weigh 5,000 tons, then the force necessary simply to overcome the inertia and move this part of the building the respective distances of 1 inch, or 1 foot, or 16 feet, in various intervals of time, is equivalent to a pressure per square foot of the exposed areas as follows:

t.	d = 1 in.	d = 1 ft.	d = 16 ft.
	Lb.	Lb. per sq. ft.	Lb. per sq. ft.
1 second	5·2	62·1	1,000
2 "	1·3	15·4	250
3 "	0·5	6·9	111
5 "	0·2	2·5	40
10 "	0·05	0·6	10
15 "	0·02	0·3	4·4

These figures will readily indicate how great a resistance the inertia of a building may offer against the motion necessary to overturn it under the action of a brief gust of wind, and how comparatively little this resistance becomes as against only such motion as is necessary to push it over on its supports. To overturn the building in ten seconds, a pressure of 10 pounds per square foot is necessary to give it the necessary motion, in addition to the force required to overcome its stability. The resistance of inertia for a movement of one foot against a gust five seconds in duration will be 2·5 pounds per square foot, and for ten seconds it will be only 0·6 pound per square foot. For shorter periods the value of inertia becomes very high, but may, on the other hand, be entirely overbalanced by the cumulative effect of the vibrations of the building acting in rhythm with the pulsations of the wind. Experiments on Chicago buildings under heavy winds show the time of a complete vibration to be about two seconds. The resistance of inertia against the destructive effect of brief but intense pressure, such as the gyratory velocities in the vortex of a tornado, is fortunately very great.

Stability due to weight alone is proportional to that weight and to the breadth of base of the support. Its value as an element of safety is a most definite one and may be sufficient. Considered with reference to overturning, a large elevator or building may be safe beyond question, yet with reference to its column supports the same structure may be in comparatively unstable equilibrium, as a relatively small movement of the center of gravity will throw it out of balance. The total force required to overturn a building of a given weight increases directly with the breadth of that building, but the total force required to push it over on its supporting columns is a constant, depending solely upon the height and breadth of base of those columns, and is independent of the dimensions of the building, of the number of supporting columns, or the material they are made of. Any structural member that is used simply as a prop or support can have only such value as is incident to that use, whether it is made of wood, of stone, of cast iron or of steel.

The elements of strength and safety inherent in a well designed cage built of the proper material, with all its members thoroughly riveted together, are present in that frame in greater or less degree, until it is torn or cut apart, piece by piece. A steel frame built to be safe for a wind pressure of 30 pounds per square foot, proportioned by unit strains of one-half the elastic limit, would probably withstand a pressure from 40 to 80 pounds per square foot before the frame yields. This range depends largely on the care with which the connections have been detailed, the extent to which possible unequal settlement of the foundations has already overstrained the frame, and on the reduction of the effective surface exposed to the wind by the destruction of the walls in the panels between the framework, leaving part of the wind to blow through unresisted.

The details of construction that provide lateral strength and safety against an assumed wind pressure are of the first importance. The subject of this paper, however, suggests a further consideration of these same details of construction, assuming that they may be strained by wind pressures beyond their safe limits. If a building is never under any circumstances to fail, the problem is completely solved as soon as it is designed to stand under the assumed pressure. Assume that it may some day be brought to the point of yielding, and immediately some pertinent questions arise as to the possible results.

While the destruction and loss of the upper section of a building may be a matter of serious consideration to the owner, the disposition which a tornado would make of that section of the building may be an equally or more serious matter to the adjoining property owners. If it is impossible to foresee the extreme force of the elements, or impracticable from economic reasons to provide against them entirely, it certainly is rational to make such modifications in a design as will reduce the possible disaster and damage to a minimum. A very material increase of safety in this direction can generally be secured at a comparatively small additional expense, depending largely on the attitude of the designer to the problem. The design of a building to be subjected safely to a given wind pressure and never to any more is a definite problem involving only arbitrarily fixed working stresses. A design of that same building for the same condition of safety, but with the further recognition of the fact that it may be exposed to destructive pressures and with an effort to develop the ultimate strength and resistance of the material in the cage to resist those pressures, is a problem that will develop some additional considerations.

A destructive lateral force exerted against the upper section of the building will not be lost or dissipated, but must follow some well-defined path till it reaches the foundation. If a building is to fail laterally, then the ultimate strength of members under the action of lateral forces becomes of the first importance. Upright members are no longer simply columns, but are more properly considered as vertical beams carrying some initial load, and, viewed in that light, must have all the essential elements of a good beam. The unequal straining and successive failure of the rivets, due to their unsymmetrical distribution in the connections, may become an important element of the design when the stresses are sufficient to overcome the averaging effect of the frictional resistance. The relative values of the ultimate or elastic limit stresses may suggest details at the connections somewhat different from those indicated by the fixed ratios of assumed working stresses.

A brief analysis of possible results applied to the definite circumstances and conditions of any particular building may suggest probable failure along one or several well-defined lines, and as readily suggest modifications that will materially increase the strength of the structure, or at least define and limit the amount of destruction.

The amount of metal required for an efficient system of wind bracing is but a small part of the weight of the metal in the entire frame, and the cost of the latter is only about 10 per cent. to 20 per cent. of the expenditure for the entire building, exclusive of the site. The cost of the wind bracing can represent, therefore, only a very small proportion of the total capital invested. When it is considered that any additional metal used to strengthen the cage as a precaution against wind force is equally effective against possible damage due to earthquake shocks, or to the unequal settlement of the foundations, and is also an additional margin provided against the weakening effect of corrosion, the slight increase in cost must appear trifling as compared to the amount of the entire investment and the additional protection secured for the property.

It is somewhat unfortunate that the merits of the design of the framework are not so readily apparent to the investor, and that this part of the structure is of necessity immediately covered and permanently concealed from view. If the difference in strength and security due to the construction of the frames of some of these great buildings was as generally evident as, for instance, the difference in strength due to the varying thickness of solid masonry walls was in older forms of construction, there would probably be a more general recognition on the part of the owners of the need of securing the best type of framework.

A discussion of the safety of high buildings is applicable to other high structures, such as chimneys, shot towers, water towers, etc., and suggests that the development of the cage construction in buildings to its present advanced type makes it equally available for other structures of the kind named above. Monuments built with no consideration of expense will find ample security in their weight, but for any high structure in which cost and security are both of importance, the cage type of construction is thoroughly applicable and may have special advantages. The saving of material in the walls, and particularly in the foundations, may more than equal the additional cost of the steel work when designed for the same strength and security. The objection to any open tower built of structural metal work in a city, on the score of its inherent ugli-

ness, is removed by adopting such treatment as the architects have developed in the design of high office buildings. Any shaft or high structure that has lines of stability can be readily supported on a steel cage that will not interfere with its outlines, with probably a great gain in safety.

The amount of wind pressure to be provided for in the design of high buildings will no doubt be variously estimated, depending on the weight given in the judgment of the designer and of the owner of the building to the probability of exposure to such pressures. The statistics as to the frequency of tornadoes show that the possibility of their occurrence cannot be entirely disregarded without assuming some appreciable risk. While the atmospheric conditions which are favorable to their formation are more common in some regions than others, it is impossible to feel assured of entire immunity from their occurrence in any city. Tornadoes usually occur as local manifestations accompanying severe storms of great extent. On the date of the Louisville tornado there were ten others in the four adjacent States. On April 11 and 12, 1896, there were nineteen tornadoes in ten States attending severe storms, reaching from Mississippi to Michigan. The St. Louis tornado was but one of a number accompanying a general storm that moved through Missouri and Illinois. As far as known, it was not more violent than many others that have been observed. Its great destructiveness was merely incidental to the fact that its path crossed a territory embracing a large and closely built city. It gave evidence that wind pressures existed at least equivalent to or greater than 30 pounds, 58 pounds, and 85 to 90 pounds per square foot over considerable areas. Whatever the actual distribution may have been, the effects were those of such pressures uniformly distributed over the areas of the respective structures. These pressures were measured by their results in exactly the same manner in which they are ordinarily assumed to act, with the consequent elimination of all uncertainties usually involved in readings of pressure gages or deductions from anemometer records, and they are to that extent positive and definite. In addition, there were indications that a pressure of somewhere from 20 to 40 pounds was quite general over a comparatively wide area in, or adjacent to, the path of the storm, and that the pressures at higher altitudes were more severe than those measured.

In view of these facts it appears to the author rational to assume:

First. That the safety and interests of the community and of the owner of the building require a recognition of a wind pressure of at least 30 pounds per square foot against the exposed surface of the building, with an additional local provision of 50 pounds for several stories near the top; and that this amount should be safely taken care of by some positive and definite provision in the construction of the frame.

Second. That the vast interests at stake, the amount of capital invested and the comparatively small additional expense necessary would suggest to the owner the desirability of increasing the provision to 40 pounds per square foot.

Third. That the other uncertain elements of safety due to the ultimate strength of the material, the inertia of the mass, and the bracing effect of walls and partitions, should be recognized only as providing against the uncertain and possibly higher pressure of the wind which may occur.

The chief justification of much that seems bold or questionable in the construction of some high buildings lies in the fact that, as yet, none have failed. If the safety of such great structures is to be determined entirely by the logic of the fitness of the survivor, based on a brief and favorable experience, rather than by a rigid analysis, by tried and accepted principles of engineering design, it may ultimately lead to some very deplorable results.

By such a test the little summer pavilion in La fayette Park must take precedence over the approach to the Eads Bridge, for it survived the tornado and is standing yet.

DUSTLESS ROADBEDS.

The West Jersey and Seashore division of the Pennsylvania Railroad system has inaugurated a new method of treating the surface of its roadbed, the object being to prevent the lifting of dust by trains. The invention, which is patented by the assistant engineer of the company, Mr. James H. Nichol, consists of the application of a heavy oil of low cost, the product of petroleum distillation. This oil being applied to the surface of the track and roadbed, including the sides of slopes in cuts, fastens the loose particles of the surface together, and prevents them being lifted by the rush of air caused by the train.

Mr. Nichol has proceeded on the theory that gravel is not only the least expensive form in which ballast may be obtained, but is also the best, provided its dust creating feature is abated. Upon the subject Mr. Nichol writes to the Railway Age as follows:

"Probably from the first building of railroads gravel such as is found along the lines of the roads has been used for ballast, and if of proper nature, porous and free from clay or loam, so as not to retain water, is one of the best substances yet used; track laid on such a foundation is elastic, therefore making the riding in cars comfortable as compared with the more rigid stone ballast. This same elasticity is a benefit to the ties and particularly to the rails, the latter, when placed on a rigid support, being in the position of a piece of metal between an anvil and a hammer, the hammer being the moving train.

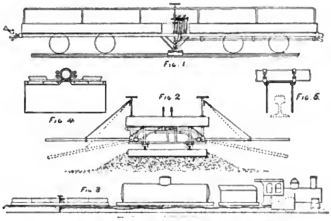
"Track laid on gravel ballast is more quickly and cheaply repaired than when on stone, the cost for ordinary maintenance and for labor in renewal of ties being about one-half.

"The principal reason for the discarding of gravel ballast on many railroads has been the discomfort to passengers arising from dust. As substitutes, various materials have been used, such as cinder from anthracite and bituminous coal, burned clay, crushed stone, etc. Each of these substances has some dust connected with its use, stone having the least. Cinder ballast is thought by some to affect injuriously the life of the cross ties, rotting the wood with which it comes in contact. Stone ballast, when first applied, and after being washed by rains, is clean and free from dust until such time as it becomes filled with material, largely cinders, thrown from the stacks of freight trains, and in this condition requires to be forked out and cleaned at large expense; the tamping of the ties, to obtain and preserve a level surface of the rails, results in the stone being crushed under the ties; and, if of a limestone character, a condition resembling a cement trough is formed under each cross tie, which catches and retains rainwater, causing the tie to decay.

"Cinder ballast, after being newly applied, requires several rainstorms to wash it free from dust, and then it is reasonably clean until the work of surfacing of track or renewing the cross ties stirs up the cinder from below the surface and exposes a new layer of dust. After a few years' use cinder becomes pulverized by repeated tampings, and is then a more objectionable dust than that from gravel, being dark in color. Experience shows that the oil produces equally good results with cinder as with gravel or sand."

The apparatus used in treating the roadbed with oil is illustrated in the accompanying engravings. For distributing the oil an ordinary flat car is fitted with one fixed pipe extending the length of the cross ties, and two swing pipes—one on each side—which, when extended, will reach two or more feet up the sides of slopes in cuts. Each pipe is controlled by a gate valve worked by a lever. A supply pipe extends the length of the car and a rubber hose connects with the four inch outlet in the ordinary tank car. A locomotive engine moves both cars and furnishes steam or compressed air to aid in ejecting the oil when thickened by cold weather. The flat car has box for tools, extra parts, etc., and is partly covered with an awning to protect the men. The sprinkling pipes are slitted for the oil to escape. The sprinkling car is furnished with shields, which cover and protect the rails from any oil which might drop or be splashed onto them. One end of the supply pipe on the sprinkling car is fitted with a connection for three or more lengths of hose, each terminating in a valve and spreader, for use by hand in covering sides of slopes in cuts.

The quantity of oil used is two thousand gallons per mile. In practice, on the West Jersey road, ordinary commercial tank cars holding six thousand gallons each are distributed at sidings about three miles apart, and are picked up as needed, the empty car being left.



OIL SPRAYING APPARATUS FOR ROADBEDS.

Fig. 1.—Sprinkling Car. Fig. 2.—End Elevation of Sprinkler. Fig. 3.—Diagram of Train. Figs. 4 and 5.—Details of Rail Shield.

The speed of the train at work is about four miles per hour.

In addition to the principal advantages claimed for the system, viz., the comfort of passengers and the reduction of wear and tear on bearing points of the rolling stock, the avoidance of hot boxes, etc., a point is made in regard to the preservation of ties and the general improvement of the roadbed, from the fact that rainwater is shed from the ties and ballast and runs off into the ditches instead of penetrating the ties and below the surface of the ballast. It is, therefore, expected that less labor will be required to keep the track in condition as to surface. The growth of vegetation in the ballast is also checked. The oil used is non-combustible, and has but little odor at first, and this is said to be lost on a few days' exposure.

The use of oil was commenced in April last. At the present time (August) there is something over one hundred miles of single track treated on the West Jersey and Seashore Railroad. The Philadelphia, Wilmington and Baltimore Railroad is building a sprinkling car in preparation for extended use, and beginnings have been made in the use of oil by the Philadelphia division and middle division of the Pennsylvania Railroad, also by the Amboy division of the same company.

Mr. Nichol gives the following account of the experience had with the treatment up to the present date:

"On the West Jersey and Seashore Railroad, which was the first to adopt the method, three months' exposure of track treated once shows a penetration in gravel ballast of three to four inches, being greatest where the gravel has least clay or loam in its composition. Walking on this ballast colors the sole of the shoe with oil; the ballast itself is not picked up on the shoe, but is pressed into the ballast beneath, a slight impression being made by the foot. When trains pass at speed no dust whatever is lifted, the track is not only practically dustless, but is absolutely so. The oil has penetrated the cross ties from one-eighth to one-half inch, according to the closeness of the grain of the wood. All of the ties are of oak.

"At a number of places track surfacing has been done after the application of the oil without creating dust, there having been a sufficient amount of ballast impregnated to prevent dust. This summer's experience has demonstrated that one application will last at least one season, and indefinitely thereafter or until ballast is broken up by renewals of cross ties. It is confidently expected that two or not more than three applications will suffice for years, as the ballast will be impregnated to and below the bottom of the cross ties, and renewals of the latter will not cause dust to be turned up."—The Railway Age.

THE UTILIZATION OF ALUMINUM IN THE ARTS.

Aluminum seems to be particularly adapted for surgical instruments and processes, and considerable has been sold for such purposes, including handles of saws, knives, speculums and surgical apparatus generally. It is not corroded by antiseptic agents. Aluminum has also been used in tracheometer tubes and metal appliances placed in contact with living tissues. Someone has an aluminum blade four inches long placed in his jaw to take the place of the jaw bone. He eats as well as ever with his aluminum jaw bone.

A bicycle called the aluminum bicycle has been sold upon the market, the whole frame being cast solid in one piece, with quite a number of the parts hollow, and frames have been made of aluminum tubes brazed together by a secret process.

A good deal of talk has been made in Europe about alkolite; another alloy is romanite. All these various alloys are mainly pure aluminum, hardened with a small percentage of other ingredients, usually less than ten per cent. The composition can readily be told by analysis in most cases. Copper and nickel, while hardening aluminum to some extent, do not render it as hard as some other ingredients. Where extreme hardness is desired, zinc, manganese and titanium give much more satisfactory results, although each, unfortunately, renders the metal more brittle than does nickel or copper alone.

In Great Britain aluminum tubes are used which are drawn on mandrels and have the advantage over the worked metal in both strength and ductility.

The Pittsburg Reduction Company have orders for casting brake shoes for 80,000 bicycles; also orders for the rims of wheels for over 100,000 bicycles.

Aluminum is being used successfully for lithographic work, the light plates being used instead of the lithographic stone, as in the past.

Lithographic work has required a peculiar stone, which is only found in special places; and the stone has to be used in thicknesses of at least an inch to two inches, and the plates are very heavy and hard to manage. With the use of light aluminum plates a very much larger number of impressions are made.

For letters and signs, aluminum has become quite extensively used, not only in the shape of fine powder or bronze, but also in heavy cast letters, which can readily be attached to glass as well as wood.

Aluminum has not been used, but has been proposed for the fabrication of passenger coaches, both in the roofs and sides of cars, as well as in the fittings around the windows. Handle bars for city railway car brakes are now made of aluminum. With handle bars made of brass, the corrosion of the metal occasions sore eyes and affections of the mucous membranes, due to the poisoning action of the copper salts.

Aluminum bronze powder is finely powdered aluminum. In the cheaper varieties now sold on the markets it is adulterated often with fifty per cent. of tin. Pure aluminum, being entirely unacted upon by sulphureted hydrogen, is more durable and superior to silver powder than the article adulterated with tin. There used to be a considerable amount of silver powder used in the arts for various purposes, where now aluminum powder has entirely replaced it.

Owing to the extreme malleability and ductility of aluminum, sheets of the pure metal are now produced of only [illegible] to [illegible] of an inch in thickness.

Cast aluminum bath tubs, sinks and similar plumbers' appliances are being made.

It is used extensively for oil cups where reciprocal motions are made, the light weight being advantageous.

The use of aluminum in the galvanizing bath has become universal to produce the best and most economical grades of galvanized work. This aluminized zinc is used in such proportions that the total amount of aluminum in the bath will be only a small proportion—about 5 per cent. of aluminum to 95 per cent. of zinc in the alloy. These proportions vary according to the grade of zinc which is used; also to the class of metal to be galvanized.

Aluminum is largely used to improve the quality of brass castings. Aluminum has been added to the brass

to strengthen it, in all proportions from $\frac{1}{10}$ of one per cent. to 10 per cent., and the best results have been obtained in using aluminized zinc (first suggested by Mr. Joseph Richards).

Adding aluminum to brass mixtures has caused the brass to give dirty castings. This really means the attempt of the aluminum to purify the brass from these properties of lead and zinc. With pure, good brass, aluminum does not form this dross nor make black, unsound castings.

Used in proportions of 5 to 10 per cent. with copper, it forms aluminum bronze, one of the most dense and strong metals known.

Aluminum has been used in the construction of yachts in the sheathing of decks; for construction above the water line, for the purpose of allowing a greater sail area to be carried without a vessel becoming cranky or top heavy. The Defender has a total saving made in the use of aluminum of over seven tons, the hollow steel boom or gaff also saving another ton. The tensile strength was 40,000 pounds per square inch, the modulus of elasticity of the metal being 11,500,000 pounds. Aluminum is being used in our navy for air port shutters in bulkheads to prevent danger from shattered pieces of flying shells.

An important use of aluminum has just been started in parts of furniture. Bookcases, rat and vermin proof, have been made, and are welcomed by public librarians.

Pure aluminum has an electrical conductivity of 63 to 64 per cent., and Prof. Richards has stated that with absolutely pure aluminum a conductivity of 66 to 67 per cent. of pure copper would be obtained. It is practically non-magnetic and may be used for purposes where a magnetic metal would be useless. Already the Pittsburg Reduction Company have finished several hundred miles of wire for telegraphic work. The use of aluminum for field military telephone and telegraph wire has special advantages. Nickel aluminum castings have been made with a conductivity of 50 per cent. of pure sheet copper. The tensile strength of ordinary copper castings is 19,000 pounds per square inch, while nickel aluminum castings have been furnished with tensile strength of 30,000 pounds per square inch.

The purest aluminum we have been able to obtain was 99·93. The purity of the commercial article as ordinarily sold is 99·30. I feel safe in making the statement that a good deal of the metal being sold is 99·60. Of copper the purest that has been made was 99·95, and the purity of the commercial metal is 99·50.

Aluminum has played an important part in the cases for compressed food, not only allowing of rapid distribution of food, but also as convenient dishes in which to heat and cook the food at the time of consumption.

Tea boxes are being made out of thin aluminum sheet weighing about $\frac{1}{6}$ pound per square foot, with angles on the inside corners for holding the sheets together.

Generally speaking, for purposes where aluminum alloy is brought into requisition in sheet form or in the shape of angles, 32,000 to 40,000 pounds per square inch may be allowed, and gives an allowable working strain of from 8,000 to 10,000 pounds per square inch. The ultimate strength of the pure aluminum is 6,000 to 7,000 pounds per square inch.

Castings of aluminum can be taken at 16,000 pounds per square inch for pure aluminum and 24,000 pounds per square inch for alloys. The pure metal should not be used in castings, except for electrical purposes, as it is very difficult to cast; is soft, comparatively weak, and has a much larger shrinkage. Alloys of 5 to 20 per cent. with copper and other metals should be used.

The ratio of the ultimate shearing strength to the ultimate tensile strength, with double riveted joints, is 70 per cent., and for single riveted joints is about 60 per cent.

The attention of those contemplating the use of aluminum for structural purposes is called to the fact that the elastic limit is closer to the tensile strength than in most other metals. Where any great strength is desired, the metal should be protected so that the temperature is not raised very much beyond that of the ordinary atmospheric air, because it melts at a little below 1,200 degrees F. For temperatures between 100 and 200 degrees Centigrade, the unit of strain should be decreased.

In the purifying of water aluminum is destined to take an important part. Alum and the sulphate have been used considerably to purify water. The active principle of alum has been the hydrate of alumina. The idea is that the gelatinous hydrate of alumina can be better produced from metallic aluminum plates immersed in water. Should the process develop, as it bids fair to, there will be a very large increase of demand for alumina. The aluminum plates being used as anodes, with the electric current passing through their ends and effecting a decomposition of the water, ozone is produced, and the electrolytic action on the water and the action of some principle in the freshly precipitated hydrate of alumina take the impurities out of the water somewhat in the form of a scum, which has really only to be seen to show how rapidly and how well the operation can be conducted.

For the ordinary coinage, aluminum, in its harder alloys, seems to be particularly well adapted. Several countries, including the United States, India and several of South America, have started to investigate the merits of the aluminum alloys for the use mentioned.

Aluminum has been extensively used in brushes and combs. There are two companies making nothing but aluminum combs. In canteens, buttons, bell plates, rings for shoulder bands, scabbard handles and shoe pegs it is largely used. One advantage in the use of an aluminum shoe peg is that there is no corrosion as there is with an iron peg.

Aluminum has been used for burial cases or caskets of various kinds.

The soldering of aluminum is found a difficult task; most of the hard and soft solders will not stick, the heat rapidly vanishing from any of the molten solders, causing them to freeze before the joint can be made. Pure tin, with a little phosphor tin, is the basis of a majority of the solders. A special solder for aluminum has been made by Edwin M. Cook, not used with any flux, simply requiring the aluminum surfaces to be cleaned and then coated with the solder.

Many fluxes have been proposed in the soldering of aluminum. Common stearin, such as is used in wax candles, has been found as efficient as any of them. Special care should be taken to clean the surfaces to be soldered, which can be successfully accomplished by any mechanical means, thus exposing fresh metal surfaces freed from the thin film of oxide of aluminum and oxide of silicon. A good plan is dipping the sheets into nitric acid diluted with three times its bulk of hot water. The solution can be kept in leaden or glass lined tanks.

Aluminum is a very sonorous metal, and is used quite extensively for gongs in the place of brass.

The first uses to which aluminum was applied were naturally those which would stand the high cost of ten to fifteen dollars per ton. This was for opera glass tubes and other optical instruments, and it was then used in thin sheets; also used in powder made from the foil in a large line of fancy goods, where the proportion of the metal was a small proportion to the total cost.

A source of failure of the metal was applying it to aluminum apparatus for heavy liquids. It will not stand more than one hundred pounds per square inch without leaking—percolating through the pores of the metal. Better strengths will be made later on to stand these heavy liquid pressures.

The lecturer would not recommend the use of aluminum at 300 degrees F. This makes it impracticable for steam boilers where the pressure is high.

The importance of aluminum in industry is emphasized by its now supporting papers devoted specially to its development, chief among which in this country is the Aluminum World (published in New York City), while there are several such published abroad.

[Continued from SUPPLEMENT, No. 1129, page 18028.]

EDWARD DRINKER COPE, NATURALIST.*

IN 1886 he received an appointment to a chair in the University of Pennsylvania and became professor of geology and paleontology. Such a man naturally awakened the interest of apt pupils, and he was a facile and entertaining lecturer. From the stores of a rich memory he could improvise a discourse on almost any topic within the range of his varied studies. His views were so much in advance of those in any text book that for his own convenience, no less than for the benefit of his pupils, he felt compelled to prepare a "Syllabus of lectures on geology and paleontology," but only "Part III, Paleontology of the Vertebrata," was published. It appeared in 1891 and is still a valuable epitome of the classification of the vertebrates, recent as well as fossil, giving in dichotomous tables the essential characters of all the groups above families and also the names of all the families. His own industry and investigations did much to render this antiquated in even six years, and a new edition or work became necessary. "Upon the Tuesday preceding his death he sent to the press an elaborate outline of his university lectures, containing his latest ideas of the classification of the Vertebrata."†

THE LATE EDWARD DRINKER COPE.

The enormous mass of publications constantly flowing from his own pen might lead one unacquainted with the author to suppose that he was probably a recluse, but there were few men of his intellectuality who were less disposed to seclude themselves. He enjoyed and gave enjoyment to intellectual company and was a brilliant conversationalist. He was especially fond of academical meetings, and was an unusually frequent attendant at the meetings of the American Association as well as of the National Academy of Sciences. His election to the presidency of the American Association was highly esteemed by him, and doubtless his address would have been a notable one.

In February (1897) Cope's health became seriously affected by nephritic disorder, which, it is said, "might possibly have been remedied by a surgical operation," but this he would not submit to. Notwithstanding failing health, he continued active almost to the last. Finally the insidious disease invaded his entire system, and he died on the 12th of April, in the room he had long used as a study, surrounded by the objects of his lifelong attentions.

Such were the chief episodes of Cope's individual life; the facts known are few, and the record belongs rather to his family than to us. But Cope's real life was in his work, and to the consideration of that work we may now proceed. Let us adopt the order in which he took up the subjects of his investigations and successively look into his contributions to herpetology (III), ichthyology (IV), mammalogy (V) and paleontology (VI); we may then examine his philosophical views, and especially those relating to evolution (VII); finally we may attempt to forecast the position he is destined to enjoy in the history of science (VIII). To know him as he was, we must recognize his weakness as well as his strength. He himself has wished this and has asked in the spirit of the Moor:

Speak of me as I am; nothing extenuate,
Nor set down aught in malice.

III.

The extent of Cope's contributions to herpetology have been referred to. Herpetology was his first love and continued to be the favorite branch of science to his life's end. His impress on it was, in some respects at least, greater than on any other of the sciences he cultivated, and doubtless the systems he introduced, with some modifications, will be the most lasting. He found herpetology an art, he left it a science; he found it a device mainly for the naming of specimens, he left it the expression of the co-ordination of all structural features. The reformations he effected in the classification of the anurous amphibians and the saurian reptiles were especially notable.

The anurans had been chiefly differentiated in groups on account of the most superficial characters. Such were the modes of fixation of the tongue or its absence, the development of disklike expansions of the tips of the toes, or simply attenuated toes, and the presence or absence of teeth in a jaw. Cope proceeded to investigate the group in an anatomical manner and reached entirely new conclusions. He found that important differences existed in the structure of the sternum, and especially in the connection of the lateral halves. In the common toads and tree toads of Europe and North America the so-called clavicle and coracoid of each side are "connected by a longitudinal arched cartilage which overlaps that of the opposite side," while in the common frogs the clavicles and coracoids of both sides are connected by a single median cartilage. The former type is now known as the arciferous and the latter as the firmisternal. Although Cope was the first to appreciate the significance of these characters, he did not at once fully realize their morphological value, the name Arcifera having been originally applied by him only to types of that group having teeth. Ultimately he did so, and his views have stood the test of time and the latest critical investigations. He also found that the characters so revealed served to fix the places in the system of the groups in question. In their early stages the Firmisternials (or frogs and their relations) have the shoulder girdle movable, and thus resemble the Arcifera (toads, etc.), which have the opposite halves movable during their whole lifetime; thus it became evident

* Presidential address by Prof. Theodore Gill before the annual meeting of the American Association for the Advancement of Science, August 9, 1897.

† Osborn in Science, May 7, p. 706.

that the latter are the lowest or most generalized forms, and the former more advanced and higher in the system. The development of teeth, which had been supposed by the earlier systematists to be of paramount value, and which Cope, following in their footsteps, had also originally unduly valued, has been found to be of quite subordinate importance.

The lizards were also in former times distributed into families and other groups on account of variations in superficial or external characters, such as the form of the tongue, the arrangement of the scales and the development of legs and feet. Cope dissected examples of all the types he could obtain and found that such superficial characters were often misleading, and he proceeded to arrange them with reference to the preponderance of all characters. The structure of the cranium especially was analyzed, and the variations and concordances in the development of various bones were tabulated. These characters were supplemented by others derived from the vertebræ, the shoulder girdle, the teeth, the tongue and the osteodermis. Familiarity with his subject enabled him almost instinctively to assess the relative values of the different characters, and he obtained fitting equations which resulted in a system which has received the approbation of the most competent judges to the present time.

The extent of Cope's influence on herpetology may be to some extent inferred from the catalogues of the richest collection of reptiles and amphibians in existence—the British Museum's. Descriptive catalogues of both the Anurans and Saurians have been published at different times. In the early catalogues are adopted the views current at the dates of publication—1845 for the lizards; 1858 for the batrachians. New editions were published many years later, and the systems of Cope were adopted with slight modifications. In his catalogue of the Batrachia salientia, Mr. Boulenger, the author, remarked that it appeared "undeniable that the principles of classification laid down by Mr. Cope are more in accordance with the natural affinities of the genera of tailless batrachians than those employed by other authors; this is amply proved by all we know of their geographical distribution, development and physiology."

In an article* published in advance of his catalogue of the lizards, Boulenger states that the old classifications are, "on the whole, as unnatural as can be," and that, "like Cope, whose lizard families I regard as the most natural hitherto proposed, I shall lay greater stress on osteological characters and on the structure of the tongue."

It was a long time, however, before Cope's views became popular. Even anatomists of repute refused to follow him. One † of them, for example, admitted that "skeletal characters are, indeed, most valuable ones in leading us to detect the deepest and truest affinities of vertebrate animals, but [he urged] these affinities once found, it is very desirable that zoological classification should not, if it can possibly be avoided, repose upon them only, but rather on more external and more readily ascertainable characters." He therefore ventured "to propose a classification derived from that of Dr. Günther."

Cope replied * by a fierce review of the work of Dr. Günther, and concluded with the utterance that such views "will only interfere with the progress of knowledge if sincerely held and believed."

But such views were evidently sincerely believed, and they did retard the progress of science. An eminent Russian herpetologist objected to the use of anatomical characters. He especially protested against those employed by Boulenger after Cope to the grouping of the lizards, and Mr. Boulenger considered it incumbent on him to defend the practice of using such characters;† he aptly replied that the use of "purely external characters . . . does not meet the requirements of modern science," and that classifications are not made simply "for the convenience of beginners."

At last, however, the principles of classification adopted by Cope have become generally accepted, and doubtless this was in no small degree hastened by their application to all the amphibians and reptiles by Boulenger.

Cope's attention to the extinct reptiles was excited by the examination and consideration of a carboniferous lizardlike amphibian which he was requested in 1865 to report upon. It was a new species which he named Amphibamus grandiceps and considered to be the type of a new order to which the name Xenorachia was applied, but which he subsequently referred to the new comprehensive order Stegocephali.

He sought for specimens of the extinct species with as much enthusiasm as he had for the recent. Extinct and living he considered together, and light was mutually reflected from the two to guide him in the perfection of the entire system. In 1869 he gave expression to the results of his studies in a well illustrated "Synopsis of the Extinct Batrachia, Reptilia and Aves of North America." This was supplemented in 1874 by addenda and a "Catalogue of the air-breathing Vertebrata from the Coal Measures of Ohio."

A rich field was opened to him in 1877, when he received the first installment of reptilian remains from Texas, which were at first considered to be of Triassic age, but subsequently determined to be Permian.

Successive installments of amphibian as well as reptilian skeletons enriched his collection, and his investigations revealed a new and wonderful fauna rich in species and often differing widely from any previously known. These were described in many articles. The results for the amphibians were summarized in 1884 in a memoir on the "Batrachia of the Permian Period of North America."

The Permian amphibians were found to vary much in the composition of their backbones. Instead of having single centra arranged in a continuous row as in existing vertebrates, they had distinct bones on which were devolved portions of the functions fulfilled by the centra of higher vertebrates. Some had "the vertebral bodies represented by three segments each, a basal intercentrum and two lateral pleurocentra;" these were named "Ganocephali" and "Rhachitomi." Some "differ remarkably from all other Vertebrata in having between the centra another set of vertebral bodies, so that each arch has two corresponding bodies;" these were called "Embolomeri."

In tracing the development of these bones, Cope came to the conclusion that they were only partially represented in higher or more specialized types; they did not become consolidated, but one or the other became reduced and finally lost or at least greatly atrophied. In the living amphibians the vertebral centra are homologous only with the intercentra, while, on the contrary, the centra of the reptiles, birds and mammals are represented by the pleurocentra of the Rhachitomes.

THE ANT EATER IN THE ZOOLOGICAL GARDEN AT STUTTGART.

The Zoological Garden at Stuttgart has for the last four years exhibited a pair of ant eaters (Myrmecophaga jubata). These are natives of South America, and belong to the family of Edentata, their jaws being quite toothless. Thanks to the great care bestowed upon them, they are in a state of splendid health, in spite of the difficulty generally experienced in keeping similar specimens long in captivity. As for breeding these animals, all attempts had proved useless until lately.

ANT BEAR AND YOUNG AT THE ZOOLOGICAL GARDENS IN STUTTGART.

But at the Stuttgart Zoological Garden, which has had similar successes before, in the way of American ostriches bred in captivity, and the pairing of a brown bear with a polar bear, there have on three occasions come into the world young ant eaters. The first comer was unexpected, and was unfortunately killed by his father. The second time they managed to keep the young animals alive for a week, and to make some observations. Once more there has been a young ant eater born, and our illustration shows him in the position he took from his birth, and kept till his untimely death—for he too was not destined to live long. He was crushed by his mother on the third day of his life.

It resembled its mother in shape and color, only the fur was shorter and softer. The claws on the forefeet, the ant eater's only weapon, were already well developed, enabling the animal to climb up on its mother's back without the least difficulty. It never left that place except when the mother lay down.

Further breeding on the part of the ant eaters at Stuttgart seems within the range of possibility.

Our illustration is taken from Illustrirte Zeitung.

The use of street cars, omnibus and city railroad lines in Berlin, Germany, has considerably increased from 1895 to 1896. In 1895 some 270,000,000 odd persons were carried by the various cars; 1896 the number rose to 311,200,000 persons, the increase being over 41,000,000. The average daily total of persons using the street cars and omnibuses in 1895 was 739,862; in 1896, 850,323 persons, an increase per day of 110,461 persons.—Glaser's Annalen.

THE SCIENCE OF HUMANITY.

By W J McGee.*

OF THE EXCELLENCE OF HUMANITY.

Humanity is a favorite theme of poet and philosopher, novelist and historian, dramatist and moralist. The changes rung on the theme run the entire gamut of human feeling and thinking; its burden is caught in song and story and crystallized in books; and no sweeter strains have ever been sung, no grander scenes enacted, no nobler lines penned, than those fertilized by the touch of human (and solely human) nature that makes the whole world kin.

The chief subject of thought among all races is humanity in some of its numberless aspects; the chief part of the literature of civilized nations relates to humanity; the chief activities of all men are inspired by humanity. Yet—and this is a modern marvel—for the greater part the thought is vague, the literature chaotic, the activity unorganized; i. e., this most important of all subjects-matter and objects-matter in human ken has hardly been brought into the domain of that definite knowledge called science. It is meet to inquire why this is so; and, to the end that the inquiry may be answered clearly, it is needful first to define humanity and then to consider what knowledge is and the way in which science has come to be; later the half formed science of that which is proper to intellectual man and most important to his kind may be outlined.

OF THE PURPORT OF HUMANITY.

According to the lexicographer, humanity denotes (1) the condition or quality of being human, (2) the character of being humane, (3) the character of being well bred, (4) mankind collectively, and (5) secular learning or literature.† The fourth of these definitions connotes man—the genus Homo, object-matter of the broad science of anthropology—viewed in a distinct way, i. e., as a mass or composite body rather than discrete individuals. The fifth definition connotes but a limited field in a vast domain, and is scholastic if not archaic; with this sense the term is chiefly used in opposition to divinity, often in the plural form (though there is good precedent for the use of this plural form in a more general and at the same time a more definite sense).‡ The first three definitions connote a wide range of attributes of man which, albeit well recognized by all intelligent people, are rarely reckoned among the objects-matter of anthropology, seldom included within the pale of science; yet it is these attributes that especially distinguish man and set him apart from the mineral, vegetable and animal worlds, and exalt him above the rocks and plants and beasts of simple nature.

Although commonplace, these definitions are worthy of careful consideration in that they summarize the substance of intelligent thought since the beginning of writing—indeed since its own beginning in the remote unwritten past—and particularly during the era of unprecedented intellectual activity and scientific progress dating from the issue of Bacon's Novum Organum; they carry the wisdom of the ages, and especially of these later days during which wisdom prevails as never before. Viewed separately or in connection with contemporary definitions relating to mankind, they indicate general (albeit vague) recognition of certain specific attributes of man, not as an animal but as an ill defined something known as a human being. When the history of thought condensed into the set phrases of the lexicographer is scanned, it is found that bitter controversy has been engendered by the diverse aspects of man as seen from opposite sides; the disputants, like the storied knights of old, have admired the object, one as silver and the other as gold, and have done doughty battle in defense of their one sided vision. The biologist, with eyes trained by observation and reason sharpened by long study of living things, sees the silvern side and sounds trumpet for man as an animal, while the litterateur and statesman and philanthropist are half dazzled by the golden glory of man as a thing supernal. The fair conclusion is that both are right as to what they see and both wrong as to what they fail to see; and in the light of this conclusion it is clear, if the general judgment of the body of thinkers is worth anything, that man has an animal basis on which a noble superstructure is borne.

The definitions of the lexicographer, who voices the thought of the world, show that among general thinkers the idea of humanity prevails over the idea of animality, while the current literature of science indicates that the idea of animality is dominant in scientific circles; indeed, some writers on anthropology, the science of man, restrict the term to knowledge of the mammalian order Bimana, a limitation excluding the essential characteristics of man as a thoughtful and emotional being and as an integral part of a collective and interdependent assemblage. Any attempt to harmonize these opposing ideas must begin with definite statement of the meaning attached to the essential term by more catholic anthropologists. So humanity may be defined, by exclusion, as the condition or quality or character of possessing attributes distinct from those of animals, vegetals, and minerals; or, by inclusion, as (1) attributes or characteristics confined to human beings, comprising (a) the condition or quality of being human, i. e., of acting, feeling and thinking after the manner of human beings, (b) the character of being humane, and (c) the character of being well bred; (2) mankind collectively; (3) learning and literature.

The supreme importance of humanity as thus defined is indicated by the fact that it is the foremost subject-matter of thought and speech and literature among all people, its prominence increasing from savagery through barbarism and civilization and culminating in enlightenment. The essential distinctness of humanity as thus defined appears when its serial relations to the other primary objects-matter of knowledge are considered. Just as living things rise above the mineral world by the possession of vitality, and just as animals rise above plants by the possession of motility, so do human beings rise above all other things by the possession of specific attributes rooting in mentality and maturing in the complex activities of collective life; or just as inorganic matter is the basis for the essentially distinct organic existence, so organic matter and processes form the basis for the essentially distinct superorganic activities of human existence. The importance and distinctness of humanity are indeed such that it behooves naturalists to recognize a fourth realm or world; to extend science from the great realms of the mineral, the vegetal, and the animal into the incomparably broader and richer realm of the purely human; and this extension is the chief end of modern anthropology.

OF THE QUALITY OF KNOWLEDGE.

Human knowledge is constantly increasing. The body or aggregate of knowledge is imponderable, and may not be counted or measured or weighed; yet it is an entity of prime importance and of universal recognition. Itself indefinite and varying from mind to mind, the sum of knowledge may be divided, albeit roughly, and analyzed, albeit crudely, and the days and years and centuries of its progress among men and peoples may be so studied that its tendencies and perhaps even the laws of its growth may be followed, albeit slowly and uncertainly. Although so indefinite, it is well worth while to try, and try again and still again, to analyze knowledge and trace its progress; for knowledge is the end and aim of intelligence, and human progress is measured not more by increase in knowledge of things than by increase in knowledge of knowledge.

Many students have found it convenient to divide or classify knowledge as individual and common, general and special, empiric and scientific, deductive and inductive, etc., according to the point of view; and these divisions are of use in that they represent first steps in analysis, though it is to be remembered that they are more or less vague or arbitrary, one or both. It may not be bootless slightly to extend this provisional analysis in order to trace more clearly the lines and stages in the growth of intellectual product.

For the sake of gaining clear ideas of relation, it is sometimes useful to project perception by the aid of mental imagery, and thereby to visualize the invisible in the eye of the mind. So the great aggregate of knowledge is often likened unto a numerical sum, or a reservoir or river fed by many affluents; but a better figure may be found in scientific ideation, and the imponderable body may be pictured as an indefinite nebula or plasma, constantly growing by accretion and constantly undergoing internal change. This plasma may best be portrayed as for the most part unorganized, with partially or completely organized nuclei and nodes and processes here and there; and there is a certain fitness in conceiving the organized tracts as near the surface, where the interactions between external and internal are direct and continuous. In this way the intellectual product of the world may be likened unto a nebula, a cloud gathering in a supersaturated solution, an ameba, or a brain—it may be viewed as a chaos more or less advanced on the way toward cosmos. The image is ideal; it serves merely as an aid in grasping and formulating widespread notions concerning knowledge as an illusive and intangible yet vigorously real and important something; but it is not essential to correct understanding of the main facts in the growth of knowledge.

Knowledge is born of the individual brain fertilized by indirect contact with other brains, and is given unto others with a degree of freedom varying with the disposition of the individual and the perfection of his mechanism for conveying thought—gesture, picture, speech, writing, printing, the growth of knowledge keeps even pace with the acquisition of structures and devices for its expression; and it is a pleasant and significant fact that in general the disposition to dispense knowledge grows strong and active just as the dispensing mechanism improves, though usually lagging a little behind—much as the verdure follows the vernal shower. So the stage of individual knowledge is initial, the stage of common knowledge consequent; so, also, individual knowledge is barren and unproductive until turned into the general fund to increase and multiply a hundredfold; and so, too, there is progressive growth from the initial stage of individual discovery or invention, through many ill-defined yet successively higher and higher steps, well toward the mature stage of general possession. It is needful to observe that the body of general knowledge can never quite equal the aggregate knowledge possessed by individuals; although stimulated by others, each active individual knows something more than he is able to tell, be he never so free in disposition and facile in expression; and it is the never-ending process of coining and issuing and exchanging the precious product of the cerebral crucible that gives rise to intellectual property right, and at the same time enriches the great plasma of knowledge and maintains the activity essential to its existence. It follows—and this scientific certitude may be commended to a certain class of socialistic schemers—that the relation between individual knowledge and general knowledge is asymptotic, and that although the latter constantly approaches, it never can reach the former; indeed, if general knowledge were ever to overtake individual knowledge, through suspension of the laws of intellectuality (undoubtedly immutable as those of vitality), the special province of mental activity would be annihilated and the body of knowledge would sink into quiescence—and, in the intellectual as in the vital, quiescence is death.

As knowledge is produced and given unto others the freedom of giving is governed by numberless conditions, including the perfection or imperfection of the mechanism for expression, the avidity or indifference of the chosen beneficiaries, and the price fixed by custom, and so it happens that certain discoveries and inventions are directly communicated only to limited groups of individuals, who thereby accumulate special knowledge. In this way cliques and trades and guilds arise and the germ of caste is planted. In this way too specialists grow up through the indifference of the masses and their inability to keep pace with the investigator whose energies are directed along a single line; and eventually, among the most enlightened peoples, special societies are formed for the purpose of fostering or diffusing discovery and invention, and thereby rounding out the great plasma of human knowledge. It may be noted that special knowledge is nearly as barren and unproductive as individual knowledge, and is soon blasted by the poison of its own egoism, unless the richer part of its substance is guided toward the general mass—to do work as it advances; for it is by no means to be forgotten that the activity of the great body of knowledge culminates in the province or zone of special knowledge, and that herein lies the leaven that leavens the whole.

During recent centuries, and especially during recent decades, specialists engaged in creating knowledge have studied knowledge itself, in the hope of learning its nature and origin; and most of these students have become convinced that the basis of real knowledge is found in the facts of the cosmos as revealed by observation or established by experimentation. So the acquisition of knowledge begins with noting particular facts and advances to assembling or grouping these facts, i. e., proceeds from observation to generalization; the second process involves the elimination of the unlike or incongruous, and this leads to discrimination and to the recognition of analogies. In general terms and somewhat provisionally it may be said that the analogies so recognized constitute laws of occurrence which may themselves be generalized, and that the requisite discrimination of analogies leads to the recognition of homologies, or laws of occurrence and sequence combined; the framing of analogies and homologies being legitimate inference, which develops in hypothesis and matures in theory or doctrine to be finally formulated in laws or principles. Knowledge produced in this regular and simple manner is commonly called inductive, though there is always a deductive element coming over from that general intellectual possession by which even the closest specialist is guided in greater or less measure. Now it is to be noted that acquisition of knowledge is largely spontaneous and unconscious—that apperception lags far behind perception, and that only the adolescent and mature among men and peoples are clearly conscious of their own mental processes, or indeed of the existence of mental process; it follows that most of the processes just outlined are ill recognized or not recognized at all, even by the very makers of knowledge. Moreover, the later steps in intellectual acquisition are commonly the first to be consciously noted; so that the majority of men, even unto the present day, have failed to recognize the true source of real knowledge, and have appealed to all manner of mysterious and extravagant sources for part or all of the intellectual wealth of the world; for, while the more complex processes alone were recognized, inference was exalted and observation was contemned, subtile imagining ran riot and overshadowed sober reason, and scholastic learning—which the practical makers of progress fortunately ignored or repudiated—grew into a labyrinth of deductions from vain postulates and hazy lucubrations. A new epoch dawned when Bacon formulated the inductive method—though he knew not that the method was old as the human mind and that he but recognized that which all men do, whether consciously or unconsciously. Reviewing the course of intellectual acquisition from observation through generalization and inference and theory unto laws of occurrence and sequence, knowledge may be classified by degree of development, and the simpler and more primitive (whether burdened by assumption or not) may be called empiric, while the more definitely organized product of special study may be called scientific; and remembering that the processes of acquiring knowledge are partly unconscious, that portion which is organized unconsciously may be classed as common sense or the wisdom of experience, while the consciously organized portion may be called science. This summary of the mode of organizing knowledge may be trite, yet it serves to show that the methods of the student of humanity are in nowise different from those pursued in the physical and natural sciences.

In brief, knowledge is ever passing from the individual to the common and from the special to the general, and thereby its quantity is constantly increased and its utility extended; during recent times it is passing also from the empiric to the scientific, and thereby its quality is improved and its beneficence multiplied.

OF THE RISE OF SCIENCE.

When the history of the class of knowledge called science is scanned, certain tendencies or directions of growth are perceived; and scrutiny shows that these tendencies are in harmony with the course of development of knowledge in general.

1. In general, observation and research begin with the rare or remote and proceed toward the common and the near. This tendency is revealed when the several branches of science are compared. Perhaps the oldest science is mathematics, which began before history, so that its origin is obscure and cannot certainly be traced to definite objective basis; but the nearly contemporary and closely related science of astronomy rested on observation of the celestial bodies—though the observation was long clouded by the mysticism of astrology. Then, as wits were sharpened by mathematical research and astronomical observation, exact knowledge was gradually brought down to nearer bodies and under the guidance of everyday observation; and thus the science of physics arose so gradually and inconspicuously that its early history is lost. Later shrewd hermits and beldams wrought magic by means of rare substances, and alchemy grew up; and as time passed the manipulations were extended to common things and the ban of secrecy was gradually broken, and so chemistry arose. These four branches of knowledge concerning the inorganic interacted with mutual benefit, and for several centuries constituted science, in contradistinction from the vast body of vague thought comprised in scholasticism and folklore and from the more useful body of commonplace knowledge not yet consciously organized. Still later attention was attracted by things nearer to mankind in place and character, and first plants and afterward animals were studied systematically, and botany and zoology arose; but for a long time the most attractive organisms were the unusual and therefore striking, or the specimens brought by travelers from distant lands—indeed, even during the present half century, scientific museum administrators are embarrassed by the tendency of the collector to neglect the common and collect the unusual in his own locality, and it is only within a generation or two that the ordinary plants and animals supplying mankind with food and clothing and other everyday

* Vice-presidential address before Section H of the American Association for the Advancement of Science, delivered at Detroit, August 9, 1897.

† Condensed and rearranged from the Standard and Century Dictionaries.

‡ E. g., in "The Humanities," by J. W. Powell; Science, new series, vol. 1, 1895, pp. 15-18.

commodities have been subjected to scientific research. In like manner the science of geology began, soon after botany and zoology, with the study of rare minerals and the ancient rocks of remote mountains; gradually the research extended to the nearer hills and valleys and the later formations; and it is only within the present generation that the soil-making deposits on which human life so largely depends have been brought under scientific examination. Last of all the scientific research beginning with the stars and passing to minerals and plants and animals, and through the soil on which plants and animals live, reached man himself; yet the studied observation began not so much with fellow citizens or fellow subjects bound to the student by ties of consanguinity and affinity as with the abject savage or half clad barbarian of distant lands; and even to-day, and in the most enlightened nations of the earth, the pictures brought up in most minds by the term anthropology are those of alien and inferior peoples, or of human curiosities and monstrosities exhibited in midway plaisances if not in circuses and dime museums. Even in scientific circles—yea, among those ranked as anthropologists—there are many who habitually restrict the term to the purely animal side of man, and ignore that broader and nobler side which distinguishes mankind from all other things. So, whether science be viewed in general or in detail, it is found that its progress is toward the Ego—toward the everyday and commonplace perhaps, yet ever toward the more important because the nearer, the more useful because the commoner; and the more nearly it approaches, the more clearly it is seen that science dignifies both student and object of study—that exact knowledge, with Midas touch, turns dross to gold.

2. In general, research begins with the abnormal and proceeds toward the normal. Judging from the habits of present day barbarians, among whom the tempest is studied and the zephyr ignored, the comet remembered and the planet forgotten, the pre-Chaldean astronomers based their first celestial observations on the erratic wanderers, rather than the orderly travelers of the sky; and in all ages prodigies—the bizarre and ill formed, the gigantic and dwarfish—have been the first to catch and the longest to hold attention among casual observers and specialists alike. This tendency toward noting the abnormal, like that of regarding the rare rather than the common, is the easily besetting sin of the touring naturalist and local museum collector, the joy of the unscientific and the despair of the scientific among museum administrators. Clearly seen in geology and zoology and botany as the vestige of a primitive past, this tendency to perceive only the abnormal is still strong—indeed, almost dominant—in the younger science of anthropology. To-day, distorted or wounded or cachectic skulls from the ancient ossuaries of Africa or the huacals of Peru are esteemed far above normal crania of a normal people who have, by normal activities, aided in making civilization and ennobling the world. To-day the platycnemic tibia and perforated humerus of questionable significance are exalted above the normal members occupied in the march of progress and the conquest of lower nature. To-day there are a flourishing sub-science called criminology and a fantastic fad of extolling and magnifying degeneracy, while the upright in mind and the sound in body are relatively neglected; yet this apparently morbid taste but reflects a tendency of the human mind, and is the promise of better things when the intellect, awakened by the abnormal, acquires the power of appreciating the normal.

Unremembered millenniums of mystical shamanism were required to produce pathology and therapeutics, and centuries of pathology were needed to produce sound physiology and etiology, and in like manner there were generations of mystical and irrational psychomancy before students were able to recognize a basis for the modern and most promising science of psychology. It smacks of the paradox to say that the beginning with the abnormal is the normal course in the making of science; yet the history of each and all of the sciences shows that the observation on the abnormal has always led attention to the normal, just as observation on the remote has ever guided attention toward the near; and it is but natural that the youngest of the sciences should yet retain vestiges of undue magnification of the abnormal.

3. In general, scientific determination proceeds from the qualitative to the quantitative. This tendency is displayed by every branch of science, and so conspicuously that it may be deemed characteristic. It is in accordance with this tendency that estimate precedes weighing and reconnaissance goes before surveying; and it is under the same tendency that scientific progress involves constantly increasing refinement in observation and ever-growing accuracy in definition.

4. In general, scientific interpretation proceeds from the formal to the physical,* from the material or the inert or the static to the dynamic. The positions and movements of the moon and planets were determined with fair accuracy before Newton discovered that the paths of these and all other celestial bodies are fixed by gravity; when this discovery afforded the means for determining position and movement with incomparably greater accuracy. The physical and chemical effects of heat were recognized for generations, and were ascribed to the hypothetic element phlogiston or the imaginary fluid caloric, long before Joule and others found it to be merely a manifestation of molecular motion; whereupon physics and chemistry were revolutionized and the forces of nature were gradually harnessed many times more effectively than before.

The ancients recognized vitality and ascribed it usually to a material something joined to the matter of the body. Some twenty four centuries ago, sagacious Heraclitus conceived life as a universal fire; and less than five centuries ago Paracelsus, and after him Van Helmont, wrote of the anima mundi or archeus, having in mind a vaguely imponderable thing akin to the so-called astral body which votaries of an Oriental belief imagine themselves able to materialize out of the depths of transcendental reverie. Two centuries ago Hoffmann and other anatomists spoke habitually of the vital fluid as contemporary physicists of phlogiston, and within a hundred years leading physiologists, like Hunter, thought and wrote of the "diffused vital material." Less than a quarter of a century ago, Barker

* As defined by Le Conte in a notable article "On the Structure and Origin of Mountains," American Journal of Science, third series, vol. xvi, 1878, page 107.

was deemed bold unto recklessness for undertaking to correlate vital and physical forces,* and many heads were shaken doubtfully when, in his presidential address before the American Association, at Boston, in 1880, the same brilliant experimentalist argued from the applications of Mosso's plethysmograph that mental force also may be weighed and measured, so that it must be regarded as interconvertible with other forms of energy;† yet half a generation of organic chemistry and physics has established these revolutionary propositions beyond peradventure, and introduced a new area of biologic research.

The tendency toward dynamic interpretation is well shown, too, in geology. In the infancy of the science, formations and the extinction of faunas were ascribed to extra-natural cataclysms, the opening of valleys and the shaping of hills to ill conceived or inconceivable catastrophies. With Lyell—a personal associate of scientific men now living—came the doctrine of uniformism, under which it is recognized that existing rains and rivers and silt-distributing waves are competent to produce the land forms and formations of the earth, provided time enough be allowed them. The present generation of geologists, beginning with Powell and including twoscore others, have scanned the pages of the Great Stone Book, so well laid open by Colorado and other rivers, and have learned to read earth history from land forms as well as formations, and have shown that at least a portion of those earth crust movements which were sheer mystery to Lyell result from the slow transfer of rock matter by the action of running water. As interpretation grew definite and the mystery of earth making dissolved, the classification gradually changed from chiefly material or static to chiefly dynamic. For a time the formations were classified by the processes of accumulation; and now the foremost geologists classify earth science primarily by the great agencies of earth making.

In anthropology, interpretation has not yet grown definite, and there are nearly as many modes of interpreting as there are men to interpret; yet, even in the short and complex history of this youngest of the sciences the general tendency appears; for the earlier classifications were based on bodily or somatic features, while the more advanced among current classifications rest either on collective attributes or on the activities of the human groups; i. e., the older classifications indicate what men are, the newer indicate what men do. Only half a generation past was it definitively suggested that human mentality is a form of energy, but already the testimony of the plethysmograph has been corroborated in so many ways and so widely extended that most scientific students of mental phenomena assume, either explicitly or implicitly, the essentially physical character of intellectual action; and in this writing it is assumed that intellectual energy is paramount, in that it is able to control other forms of energy and make conquest of nature through invention and construction, and the faculties and works of man are classified and interpreted accordingly.

So in astronomy and physics and chemistry, and equally in biology and geology, the progress of science may be measured by the ever increasing recognition of the dynamic aspect of phenomena, of the physical forces by which the material things are moved; with the recognition of inherent energy or motion, observation progresses from the merely qualitative to the quantitative, and constantly increases in refinement; and in view of this progress in other sciences, it can hardly be regarded as premature to attempt the extension of quantitative measure and dynamic interpretation to that side of anthropology which deals with the purely human attributes.

5. In general, scientific interpretation progresses from the stationary to the sequential; for the idea of action engenders the idea of succession. The Chaldean shepherd, the Egyptian soothsayer, and the Peruvian priest, like the earlier oriental astrologer, probably first took note of the celestial bodies as striking features of the cosmos, and later observed their rhythmic procession with such care that cycles were established and eclipses and other prodigies were foretold long before the true structure of the solar system was understood. These ancient observations and interpretations must have implanted that idea of the uniformity of nature which has borne so splendid fruit during the present century; the budding notion found poetic expression in pleasing fancies of firmaments of crystal and the music of the spheres; yet it was not until the germinal idea was fertilized by the Newtonian law that the marvelous measure of celestial rhythm came to be known. Led by the planless experiments of daily toil, the mechanic—forerunner of the physicist—was the next to lay hold on the notion of uniform succession; it grew with the centuries and spread into the neighboring domain of chemistry, where it vitalized the dynamic interpretation of chemic union, and aided in producing Avogadro's law, which, according to Cooke, "holds the same place in chemistry that the law of gravitation does in astronomy"‡ and forms the basis of what has justly been called the new chemistry. This law, like all others in science, afforded a means of prevision, or of presaging the unknown in terms of the known, and thus of testing its own validity; and as test followed test the idea of orderly succession grew until, with the aid of refined observation and the guidance of special experiment, it matured in the doctrine of the persistence of motion, the keynote of modern science. Here was a vantage point from which the astronomer was enabled to study the celestial bodies, especially our own sun, not merely as masses, but as chemical and physical assemblages; and so arose the line of research sometimes called celestial physics, but defined and dignified by Langley as the new astronomy,§ which has already afforded a means of analyzing the constituents and measuring the movements of several among the myriads of other suns than ours. True, each of these strides in the advance of physical science represents progressive appreciation of cosmical forces; yet still more fully do they represent progress in recognizing orderly sequence and causal succession in the movements of molar and molecular bodies.

* "The Correlation of Vital and Physical Forces."—University Series, No. 2 (Van Nostrand), 1875.

§ "The New Astronomy," 1888, chapter I.

Borrowing from physical science trenchant ideas concerning force and succession, even the earlier biologists analyzed the mechanism of living things and slowly stripped away the primitive panoply of mystery or divinity in which the infantile imagination, whether of men or races, has always enveiled vitality. Lamarck was one of the first to extend the idea of orderly succession to organisms, and although his special hypothesis of development has fallen into abeyance it has features which anthropologists do well to remember; then came patient Darwin and doughty Huxley and studious Spencer with the definite doctrine of organic evolution, which spread from man to man and from land to land, producing the greatest and quickest intellectual revolution in the history of the world. Albeit revolutionary, the Darwinian doctrine was but the biotic complement of the physical doctrine of the persistence of motion, and the two doctrines are twin buttresses on which the symmetric structure of modern science is supported. Through the later doctrine the world and the things thereof were transfigured in a new beauty and perfection, the universe was invested with a new glory, and the narrow notion of breaks in the uniform course of nature by special fiat lost hold on the scientific mind forever.

It chanced that while the ferment of evolution was still fresh, a trio of American geologists—Powell, followed by Gilbert and Dutton—entered the inspiring region traversed by Colorado canyon, and before their work was done the germ of geomorphy, or the new geology, was planted. It was realized more clearly than ever before that the hills are not everlasting but everchanging, and that the features of every landscape tell an eloquent tale of continental evolution in which competent cause and commensurate effect follow ever in ceaseless succession through the eons of earth making. The task of the geologist is not ended, indeed, is only well begun; yet here, as in other sciences, the reign of law is realized, and the day of appeal to chance is past.

When Huxley sought "Man's Place in Nature,"* and still more when Darwin traced "The Descent of Man,"† the fruitful idea of the uniformity of nature was pushed into the domain of anthropology, and has now guided for a generation those branches of the science which deal with the animal side of man; it is true that the rhythmic sequence of cause and effect has hardly been extended so far as to cover the delicate and elusive attributes of humanity, but this extension is the motive of many investigators, the aim of the present writing. Already the broad realm of humanity is fairly defined, and the distinctive form of developmental succession proper to this realm is fairly outlined, so that the distinctness of the science of human attributes has been made clear; for while stellar and molecular and organic development are evolutionary in that the main tendency of change is toward differentiation, the development of humanity is involutionary, in that the main tendencies are toward integration and combination. Conformably to the fundamental facts of the great realms of nature, the earlier sciences are largely, perhaps chiefly, analytic, while the science of humanity is largely, perhaps chiefly, synthetic, and its votaries seem to find reason for figuring it as the central dome crowning and conjoining the separate columns in the ideal pantheon of science. If the confidence of the votaries is just, the youngest of the sciences may be expected to repay with interest all that it received from the several branches of knowledge whence it sprang. Already, indeed, it has thrown light on the course of organic development through researches on the human body, and has begun to guide the acquisition of knowledge through researches on the human brain and its functions; already it is contributing to the physical sciences, e. g., through the refreshing Powellian doctrine of conservation, or of common persistence of motion and matter in the ultimate particle, whereby ideas concerning the mechanism of the universe would seem to be immeasurably simplified and extended; and there are other ways in which the youngest science is daily contributing to the stock of definite knowledge. Their name is legion.

So it is that science has always progressed from the rare to the common, from the remote to the near, from the abnormal to the normal, from the merely qualitative to the quantitative, from the merely material aspect to the physical aspect, from the primitive faith in fixity to living realization of causal succession. At first sight this progress may seem puzzling, even paradoxical, yet the general course is but an expression of the order of intellectual operations pursued in scientific research. The first step is observation; it is easy when the objects observed are isolated or distinct, and increasingly difficult as the objects increase in number and similarity. The second step is generalization, which is relatively easy when the objects examined are few, relatively difficult when they are many; while the ancillary process of discrimination of the incongruous likewise grows laborious with the multiplication of objects and similarities. Accordingly it is easy to study the rare, the remote and the abnormal, and as faculty is strengthened by exercise, gradually it becomes easy to progress toward the common, the near and the normal. So also qualitative determination is easy, quantitative determination difficult—indeed, exact quantitative work is impossible without careful training, as numberless surveyors and teachers can testify. In like manner interpretation in terms of the material, coupled with appeal to the supernatural when obstacles are encountered, is relatively easy and characteristic of the indolent or immature mind, while the firm grasp of analogy and homology, and the clear recognition of energy and sequence, require both native capacity and systematic training. Accordingly scientific interpretation in terms of action and succession is the end of mental effort, and may be regarded as the highest expression of intellectuality. This correspondence between the method of research and the history of science throughout the centuries amply attests the excellence of the method. Yet it is not to be forgotten that just as intellectual grasp strengthens so interpretation is simplified, partly through the elimination of that question-begging mysticism which pervades all primitive philosophies, partly through clearer arrangement of facts and relations. And as

* First publication in 1863.

† The first edition of this notable work appeared in 1871.

interpretation grows simple three especially noteworthy effects follow: (1.) Each step in interpretation makes the later steps easier. (2.) As the labor lightens, more energy is left for the next task, and the mind of the student pushes into new fields of study and from time to time organizes new branches of inquiry; and (3.) With each extension of inquiry mental faculty is stimulated and strengthened. These tendencies are clearly indicated by the birth and growth of new sciences recorded in the history of research; beginning with the celestial bodies, it has extended to mechanical bodies, vegetals, animals, the earth itself, then to the human body, individual and collective; and now it is reaching out toward the special attributes of mankind, the things nearest to human welfare and happiness.

(To be continued.)

SELECTED FORMULÆ.

Depilatory.—

(1.) Sodium sulphydrate	100 grains.	
Slaked lime	80	"
Starch	30	"
Lime water	4 fl. dr.	

With the aid of water this powder is converted into a soft paste, and applied to a hairy skin in a layer as thick as a straw. After drying about ten minutes, the pellicle is scraped off with a paper knife, or similar blunt instrument, and with it the hair. The face should be washed clean and anointed with some bland oil.

Sodium sulphydrate is prepared by supersaturating at ordinary temperature a solution of sodium hydrate of specific gravity 1·35 (made from 1 av. ounce of caustic soda and 3 fluid ounces of water), and then setting aside the well closed jar for several days in a cold, dark place, when the crystals formed may be removed and preserved in a well closed vial, protected from the light.

(2.) Orpiment	1 part.	
Slaked lime	5	"
Starch	8	"
(3.) Quicklime	120 grains.	
Sodium sulphide	240	"
Starch	80	"
Orris root, powder	40	"

Rub the necessary portion of this powder into a thin paste with water, and apply as directed for No. 1. —Pharmaceutical Era.

Cholera and Diarrhea Remedies.—We give below a number of desirable formulas from which you may select one or more to suit your needs:

SUN CHOLERA MIXTURE.

Tincture of opium	1 part.	
Tincture capsicum	1	"
Tincture rhubarb	1	"
Spirit camphor	1	"
Spirit peppermint	1	"

SQUIBB'S DIARRHEA MIXTURE.

Tincture opium	40 parts.	
Tincture capsicum	40	"
Spirit camphor	40	"
Chloroform	15	"
Alcohol	65	"

AROMATIC RHUBARB.

Cinnamon, ground	8 parts.	
Rhubarb	8	"
Calumba	4	"
Saffron	1	"
Powdered opium	2	"
Oil peppermint	5	"
Alcohol	q. s. ad 100	"

Macerate the ground drugs with 75 parts alcohol in a closely covered percolator for several days, then allow percolation to proceed, using sufficient alcohol to obtain 95 parts of percolate. In percolate dissolve the oil of peppermint.

RHUBARB AND CAMPHOR.

Tincture capsicum	2 ounces.	
Tincture opium	3	"
Tincture camphor	3	"
Tincture catechu	4	"
Tincture rhubarb	4	"
Spirit peppermint	4	"

BLACKBERRY CORDIAL.

Blackberry juice	1875 c. c.	
Cinnamon, ground	100 grms.	
Cloves, ground	25	"
Nutmeg, ground	25	"
Diluted alcohol	q. s.	
Sirup	1875 c. c.	

Percolate the ground drug with diluted alcohol to obtain 1,250 c. c. of tincture, and to this add the blackberry juice; then add 30 grm. purified talcum, set the mixture aside for 24 hours, and filter. Wash the filter with sufficient diluted alcohol to obtain 3,125 c. c. of filtrate and add the sirup.

BLACKBERRY MIXTURE.

Fluid extract blackberry root	2 pints.	
Fluid ginger, soluble	5 1-3 ounces.	
Fluid catechu	5 1-3	"
Fluid opium for tincture	160 minims.	
Brandy	8 ounces.	
Sugar	4 pounds.	
Essence cloves	256 minims.	
Essence cinnamon	256	"
Chloroform	128	"
Alcohol (25 per cent.)	q. s. ad 1 gallon.	

—Pharmaceutical Era.

Wild Cherry Phosphate.—

Simple sirup	5 pints.	
Fine sherry wine	2	"
Depurated German cherry juice	10 ounces.	
Fluid extract wild cherry	3	"
Solution of phosphates	2	"
Fruit acid	1	"

Mix well together and filter.

For dispensing, draw a tumbler seven-eighths full with soda water; then add two ounces of this sirup, stir with spoon and serve.—Practical Druggist.

THE TRIAL OF THE MARCONI TELEGRAPH AT SPEZIA.

TELEGRAPHY without wires is still the all-absorbing topic of the day, and, therefore, although we have already published considerable about Marconi and his work, we feel sure that our readers will be interested in the accompanying engravings, one of which is a portrait of Marconi, while the other shows him as he appeared when receiving messages during his experiments at Spezia, the receiving apparatus being on a moving boat. He was assisted at this time by the electricians Civita and Pasqualini, whose portraits we also have in this engraving.

These experiments, which lasted three days, July 11, 12 and 13, were conducted on a large scale by order of the naval department, so that the full scope of the invention might be understood. On the 11th the experiments were made between the San Bartolomeo Arsenal and the offices of the department, a distance of about two and one-half miles; on the 12th the experiments were public; and on the 13th messages were sent from one moving vessel to another, care being taken to have obstacles between the vessels, as it was desired to prove beyond a doubt that no obstructions of any kind would interrupt communication. L'Illustrazione Italiana publishes the following report of the trials made on the 12th:

"The experiments took place at the arsenal at Spezia; Marconi and the electrician Civita remaining at the receiver, which was placed near the entrance of the headquarters, while Prof. Pasqualini, of the department of electricity and war supplies, stood by the transmitter, outside of the directors' room at the arsenal. Before beginning the experiments Civita explained the apparatus. The results were splendid, as they always are. Various phrases were transmitted, such as 'Evviva Marconi,' 'Evviva Bologna.' (The latter is the native city of the young inventor.) Several officers of the navy, the engineer corps and the artillery addressed questions to Marconi, who answered them all, although tired from the excitement and work of several consecutive days. Admiral Grillo presided, assisted by the commander of the Spanish vessel Cristobal Colon."

SIGNOR MARCONI.

In speaking of his own work, Marconi says:

"The greatest distance to which we have been able to transmit messages by telegraph without wires is twelve miles. But that by no means is the limit of the instrument; it simply signifies that existing appliances are not perfect. At Spezia I sent messages without wires from the San Bartolomeo arsenal to the war ship San Martino, twelve miles out in the harbor, without difficulty and with absolute accuracy. It was done before the royal commission. Official experiments will be renewed when I return to Italy in September. I have successfully experimented also at the Italian Ministry of Marine and at the Quirinal before the King and Queen. I made the discovery almost by accident. I had been studying electrical phenomena three years, when two years ago I found that by putting Hertz's radiator to the earth, connecting it with a wire extended vertically in the air and repeating the process with the modified Branley receiver, a current could be transmitted about one hundred yards without connecting the wires. Then I found that, without increasing the battery power but by simply increasing the height of the vertical wire, the influence of the instrument extended over a distance increasing in geometrical ratio to the increased height of the wire.

"The wire must extend into the air. A coiled wire helps only as the coil is high, not according to the length of wire in the coil. A wire inclined instead of vertical has power equal only to that developed by a vertical wire as much shorter as the distance taken up by the inclination. A wire carried to the top of the high mast of a ship ought to enable the captain to telegraph a considerable distance, figuring that 100 feet in height of the wire means twelve miles in distance of communication. By the same process magazines could be exploded in time of war from a great distance, and signals could be sent so that the enemy could not possibly interrupt communication. It has been said that this would work both ways, that a current radiates in all directions from the sending instrument and, therefore, that a message would go to the enemy's camp as well as to a friend's. But this can be easily prevented, as I have proved, by means of electrical reflectors, which would arrest the progress of a message in all directions but one. I am not certain that I shall ever be able to send messages across the Atlantic, but I can see no reason why I should not do so, if I can increase the height of a vertical wire enough. I am just as much in doubt as you are as to the reason for this strange influence of a vertical wire over the strength of a current in this new development of that most mysterious of all agents, electricity. It will not cost more than half as much to install a telegraph system on my plan as it would on the old system. The instruments are slightly more expensive, but I imagine a decrease in cost would be brought about by the absence of miles of wire and poles."

EXPERIMENTS WITH THE MARCONI TELEGRAPH—THE RECEIVING APPARATUS IN A BOAT AT SPEZIA.

W. H. Preece, electrician to the British post office, made the following report of the experiments in England last year by Marconi:

Mr. Marconi utilizes electric or Hertzian waves of very high frequency, and they depend upon the rise and fall of electric force in a sphere or spheres. He has invented a new relay which for sensitiveness and delicacy exceeds all known electrical apparatus. The peculiarity of Mr. Marconi's system is that, apart from the ordinary connecting wires of the apparatus, conductors of very moderate length only are needed, and even these can be dispensed with if reflectors are used. His transmitter is Professor Righi's form

of Hertz's radiator. Two spheres of solid brass four inches diameter are fixed in an oiltight case of insulating material, so that a hemisphere of each is exposed, the other hemisphere being immersed in a bath of vaseline oil. Two small spheres are fixed close to the large spheres and connected each to one end of the secondary circuit of the induction coil, the primary circuit of which is excited by a battery, thrown in and out of circuit by the Morse key. Now, whenever the key is depressed sparks pass, and since the system contains capacity and electric inertia, oscillations are set up in it of extreme rapidity. The line of frequency of oscillation is probably about 250,000,000 per second. The distance at which effects are produced with such rapid oscillations depends chiefly on the energy in the discharge that passes. A six inch spark coil has sufficed up to four miles, but for greater distances we have used a more powerful coil—one emitting sparks twenty inches long. It may also be pointed out that this distance increases with the diameter of the spheres, and it is nearly doubled by making the sphere solid instead of hollow.

"Marconi's relay consists of a small glass tube four centimeters long, into which two silver pole pieces are tightly fitted, separated from each other by about half a millimeter—a thin space which is filled up by a mixture of fine nickel and silver filings, mixed with a trace of mercury. The tube is exhausted to a vacuum of four millimeters and sealed. It forms part of a circuit containing a local cell and a sensitive telegraph relay. In its normal condition the metallic powder is virtually an insulator. The particles lie in disorder. They lightly touch each other in an irregular method, but when electric waves fall upon them they are polarized, and order is installed. They are marshaled in serried ranks, they are subject to pressure—in fact, they "cohere"—electrical contact ensues and a current passes. The electrical resistance of Marconi's relay—that is, the resistance of the thin disk of loose powder—is practically infinite when it is in its normal or disordered condition. It is then, in fact, an insulator. This resistance drops sometimes to five ohms, when the absorption of the electric waves by it is intense. It, therefore, becomes a conductor. Marconi "decoheres" by making the local current very rapidly vibrate a small hammer head against the glass tube, which it does effectually, and in doing so makes such a sound that reading Morse characters is easy. The same current that decoheres can also record Morse signals on paper by ink. The exhausted tube has two wings, which, by their size, tune the receiver to the transmitter. Choking coils prevent the energy escaping. Oscillations set up in the transmitter fall upon the receiver tuned in sympathy with it, coherence follows, currents are excited, and signals made.

"In open, clear spaces within sight of each other nothing more is wanted, but when obstacles intervene and great distances are in question height is needed, and tall masts, kites and balloons have been used. Excellent signals have been transmitted between Penarth and Brean Down, near Weston-super-Mare, across the Bristol Channel, a distance of nearly nine miles. Mirrors also assist and intensify the effects. They were used in the earlier experiments, but they have been laid aside for the present, for they are not only expensive to make, but they occupy much time in manufacture. It is curious that hills and apparent obstructions fail to obstruct. The reason is probably the fact that the lines of force escape these hills. Weather seems to have no influence; rain, fogs, snow, and wind avail nothing." For our engraving we are indebted to L'Illustrazione Italiana, and for our portrait to the Illustrirte Zeitung.

SECTORLESS WIMSHURST MACHINES.*

By S. M. KEENAN.

THERE exists a prevailing idea that sectors are absolutely necessary on a Wimshurst influence machine, while in point of fact they are somewhat of a detriment when a large output and long sparks are required. The only objection to sectorless machines is their inability to self excite. This is a minor consideration in a large machine, as a charge is readily imparted and can be retained, often for hours, while the machine is idle. A rod of vulcanite, gutta percha, glass, wax, etc., excited by any of the well known methods, and held opposite the neutralizer, easily imparts a charge. Any particular sign can be given to either side. If the machine be incased and it is not desirable to open the case, a small self-exciting machine may be placed in the case or under it and proper connections made with the prime conductors. These connections, likewise the attachments for imparting motion to the exciter, may be controlled from the outside. Similar arrangements are made use of by Waite & Bartlett, by Van Houten and by Ten Broeck to excite their large Holtz machines.

The only requirements necessary to change a sectored to a sectorless machine is to attach several brushes or points to each section of the neutralizer and discard the sectors. It makes little difference whether brushes or points are used, the results are about the same. When brushes are used they gradually wear off and require renewing, whereas points are free from this objection, as they do not touch the glass. Points, however, require very careful adjustment, particularly in large machines with multiple plates, as they are liable to scratch the shellac off the plates or perhaps fracture them. The more of the radial surface brushed or that passes in front of the points, the greater the output. There is, however, a limit, as a spark is liable to jump from one collector to the other by way of the neutralizer if the end of the latter is very near the center. A little experimenting will soon give the proper positions. To adapt the machine for the production of long, thin sparks, or short, thick ones, it is well to provide adjustable neutralizers and collectors.

The first published notice of a sectorless Wimshurst appeared in La Nature April 14, 1894. The machine therein described is the embodiment of an idea suggested by M. Pellissier in 1891 in the Journal de Physique. This machine, constructed by Mr. Bonetti, appears to have been preceded by one made by A. J. Picolet. The essential features of both are the same, the only difference is that Mr. Bonetti used several brushes on the neutralizer, while Mr. Picolet employed points. Mr. Bonetti's machine measured by a Lane electrometer, according to the authoritative statement of Mr. D'Arsonval, who carefully tested it, "gives a discharge three times greater than a machine of similar dimensions provided with sectors." Illustrations and full descriptions of Picolet's and Bonetti's machines may be found in the SCIENTIFIC AMERICAN, May 26, 1894.

The writer was constructing a two-plate, 18 in. machine, when the description of Bonetti's machine appeared, and decided to try it before the sectors were placed on the disks. A rubber comb passed through the hair once or twice excited the machine, but the discharge was insignificant, due to the small surface brushed, there being employed but the four brushes as used on the sectored machine. When the room was darkened the glow appeared only in the region of these brushes. A wire was then passed diametrically across the plates on each side and fastened to the ends of the neutralizing rods. Tinsel brushes were attached 1 in. apart on

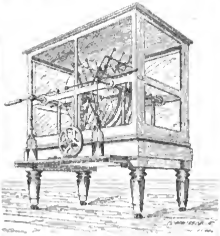

FIG. 1.—SECTORLESS WIMSHURST MACHINE.

the wires and pressed gently against the glass. By this arrangement almost the entire surface of the disks was brushed. Upon exciting the machine the effect was magnificent. Powerful sparks 8 in. long passed between the knobs.

An adjustable neutralizer has been substituted for the temporary wires. This machine never fails to work when a Voss or regular Wimshurst will excite. Some days during the summer when the atmosphere is very humid it will not work, nor will any other, unless it be incased and drying material placed in the case. Under similar conditions, with an exciter in the case, a sectorless machine will work during any weather. There are two sets of plates for this machine, one with and one without sectors. But a few moments are required to change it from one to the other. Careful comparisons have been frequently made, with the result always greatly in favor of the latter.

A 40 in., two disk, sectorless machine was constructed last year for Roentgen ray work, but it is not suitable for exciting Crookes tubes, owing to the small output in current. Two things are essential for exciting Crookes tubes with a static machine—multiple plates or very high rotary speed. As 40 in. glass disks cannot be thus rotated, it can easily be seen why this machine is unsuitable for Roentgen experiments.

The writer has lately constructed a twelve-plate, 32 in. diameter, sectorless machine, which answers so perfectly every purpose of experiment and electro-therapeutics that a brief description may prove of some interest. Fig. 1 gives a general idea of the machine, with the exception of the exciter, which is not shown in the sketch. The driving pulleys and bosses are the same as on an ordinary machine, with the exception that the steel shaft for the pulleys turns in roller bearings. The rest of the machine is entirely different from Wimshurst's. The base frame is made of $3\frac{1}{2} \times 3\frac{1}{2}$ in., kiln-dried yellow pine, and mounted on suitably turned legs. This base gives a very firm foundation to the machine and prevents the glass case from shaking

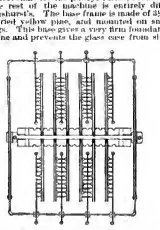

FIG. 2.—SECTION OF NEUTRALIZER.

when the machine is working. Two uprights are bolted to the inside of the side pieces and are slotted at the top to receive the steel shaft carrying the plates.

Fig. 2 shows a section of the adjustable neutralizer. This consists of a rectangular frame that passes entirely around the plates and is mounted on the disk shaft by double knobs. These knobs are tapped for a piece of tubing the same size as the bushing of the bosses and serve as bearings for the shaft. Taper-bored ball nuts are fitted on each end of the cross arms and hold the transverse rods near or remote from the edges of the plates. The radial rods that carry the brushes are mounted on the transverse rods by cross-bored knobs that slide on the transverse rods. By means of set screws these knobs may be set in any position; likewise the radial rods. By this combination, which was made purposely for wide adjustments in experimenting, the neutralizers may be placed at any angle, the radial rods may be all raised or lowered together or separately, and, in fact, any adjustment desired may be made in a moment. This rather complex neutralizer adds considerably to the expense of the machine, but is very desirable when careful investigations are required. The radial rods carry alternate brushes and points set $1\frac{1}{2}$ in. apart, and brush any portion or all of the plate as desired. The brushes and points are interchangeable, and hence brushes alone or points alone may be used.

The prime conductors (see sections, Figs. 3 and 4) are supported on vulcanite posts and the discharge rods fitted into either ends of these conductors, affording the use of the dischargers from either side of the ma-

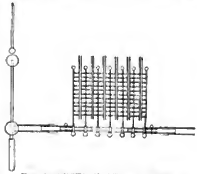

FIG. 3.—SECTION OF COLLECTOR.

chine. The collecting combs are adjustable up, down and sideways on the prime conductors. As window glass plates of large size are more or less "dished," this arrangement of the collecting combs is desirable owing to the fine adjustment it affords.

The Leyden jars may be placed inside the case or outside on a movable shelf. The external coatings of the jars are connected underneath the shelf by a sliding switch that protrudes therefrom close to the hand of the operator, enabling him to produce the spark or brush at pleasure. Two binding posts are connected to either portion of the switch for administering an induced current or for attachment to the primary of a D'Arsonval or similar high frequency transformer. These binding posts carry sliding dischargers for the regulation of the induced spark. By these the induced current may be made to assume a continuous or an interrupted oscillation. By them the volume of the direct discharge may likewise be controlled to a nicety. This has been found very serviceable in Roentgen ray experiments in conjunction with a regulated spark gap in the main circuit. When a Crookes tube is placed in the direct circuit—the best method by far—and the induced circuit closed, fitful sparks generally pass across the gap, rendering the illumination of the tube very bright but inconstant. If the induced circuit be opened beyond sparking distance, the discharge at the gap will be constant, but often too weak for powerful excitation of a tube of high vacuum. But, if the induced dischargers be separated gradually, a point will soon be found at which the tube becomes brightly fluorescent and very constant, giving rise to abundance of Roentgen rays which render quite distinct in the fluoroscope the shadows of the deeply seated bones.

The case is made in two sections and may be removed at pleasure, as the operating parts of the machine are constructed independent of the case. To remove the case, the key bolts for holding the dischargers to the prime conductors are removed and the dischargers taken off, the hooks at the top of the case opened and each half section lifted off the base separately. This is particularly advantageous for the purpose of replacing broken disks.

This machine has been in operation for three months in the Wayne County (Mich.) hospital, and has given the very best of satisfaction to the physicians in charge. It embodies all the latest features for electro-therapeutic treatment and has proved a valuable remedial agent in many diseases. With suitable Leyden jars it produces powerful sparks 15 in. long and abso-

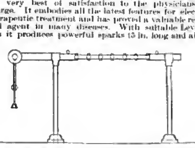

FIG. 4.—SECTION OF PRIME CONDUCTOR.

lutely deafening. When a patient is placed on the insulated stool, connected with one of the dischargers, and the outside coating of the jars disconnected, powerful brush discharges several inches long and entirely painless may be drawn from any part of his body. For Roentgen ray work it is excellent. Its enormous output, suitably regulated, renders the largest tubes intensely active with perfect ease. Nor does it dangerously heat up a tube—the great fault of induction coils; after using it constantly for two hours or more the tube remains comparatively cool.

There are, no doubt, about this machine many features that may be greatly improved, rendering it thereby much more efficient, for it is exceedingly difficult to construct anything along lines of a radical departure and avoid errors.

* From the American Electrician.

DESCRIPTION OF A CLOSING TOW NET, FOR SUBMARINE USE AT ALL DEPTHS.*

By C. H. TOWNSEND, Assistant, U. S. Fish Commission.

RECENT experiments with closing tow nets in submarine explorations have yielded so much accurate information concerning the vertical range of pelagic life, that the construction of the Tanner intermediate tow net in 1891† may be said to have inaugurated a new era in the study of the pelagic fauna, characterized by exact knowledge of the depth of the forms collected.

The vertical distribution of the pelagic life gathered with the open tow nets of the Challenger expedition has necessarily been conjectural, the nets employed having been dragged open at all depths. Since then European investigators have employed several devices for closing submarine tow nets, but direct evidence as to their reliability, so far as the writer is aware, seems to be lacking.

Open tow nets of different forms have long been employed by the United States Fish Commission, while a closing collector, although of very limited capacity (the Sigsbee gravitating trap), has done service on the Coast Survey steamer Blake; but it was not until 1891 that a closing tow net of large size was brought into use. The Tanner tow net, closing tightly at any depth desired, has proved its efficiency during recent explorations conducted by the Fish Commission and by Mr. Alexander Agassiz, but its large size and somewhat complicated construction have prevented its use except by steam power from large vessels.

While towing a light surface net behind one of the small boats of the Albatross in an Alaskan harbor in the summer of 1894, the idea of a very simple closing net presented itself, which was at once experimented upon and gave satisfactory results. I at first used it in moderate depths only, but subsequently, having made one of heavier form than at first employed, the principle was found applicable to deep sea work as well as near the surface.

This form of towing net is, on account of its lightness and simplicity, convenient for use by hand from all kinds of small sailing craft and open boats. It can be rolled into a small package with all its attachments and carried readily in one hand. With a light tow line passed through a pulley slung from one of the boat davits of the Fish Commission steamer Albatross, it has been hauled in from depths of 20 and 30 fathoms by one man with very little exertion, and has not failed to work in a single instance.

In the summer of 1895 this net, constructed in larger and heavier form, with a net ring 3 feet in diameter, was used successfully on board the Albatross during fishery investigations in Bering Sea, at depths varying from 20 to 200 fathoms.

Following is a description of a closing net of medium size constructed for use on the Fish Commission schooner Grampus (Pl. 1, Figs. 1 and 2). It consists of a tow net with a folding ring suspended by rope slings from a tripping arm attached to the tow line, and is operated at will by a messenger. The ring to which the net is attached is hinged to fold, for the purpose of closing the net, and is supported by two sets of slings of nearly equal length, one set attached near the hinges, supporting the net in an open position, the other attached at right angles to the hinges, supporting it in a closed position.

Closing is effected by means of a tripping arm, from which the slings are suspended, and which, being tripped by a messenger, shifts the weight from the opening to the closing slings, with the result of closing the net. The tow line is attached to the lower end of the tripping arm, the upper end of which is hooked to a ring on the tow line. The opening slings are secured near the upper end of the arm, the closing slings to the lower end. A light messenger (Pl. 1, Fig. 3) sliding down the tow line detaches the messenger ring from the upper hook of the tripping arm, shifting the weight from the opening to the closing slings. A spring catch in the upper hook of the tripping arm keeps the messenger ring from slipping out of place until struck by the messenger, while a heavy ring-shaped weight, released by the tripping of the arm, slips from the lower hook of the arm down the closing slings and keeps the jaws from opening after they have been closed by the messenger. The accompanying figures, showing the net in both open and closed positions, illustrate its workings clearly.

The tripping arm is merely a piece of half-inch brass, ordinarily about 2 feet in length and of the shape shown in the cut. The ring is 2 feet in diameter, made of ⅜ by ¼ inch brass, and is essentially the same as that employed by Agassiz for use with his modified Chun-Petersen machine.* The messenger is a 2 pound bronze casting, in two parts, to lash around the tow line. A small lead sinker is lashed to the bottom of the net, of sufficient weight to carry it down clear of the ring, as it is, of course, lowered vertically and the vessel from which it is operated brought to a full stop. The net is light and of small mesh, preferably half inch. It is lined with bobbinet or mosquito netting, with a delicate inner lining of silk bolting cloth, the last being the real collector, to which the outer nets act as supports.

In this combination of three nets all are of full width to the bottom, where they are closed by a lashing, the inner nets being secured rather slack, in order to avoid strain upon them in towing. As used on board the Albatross, by steam power at all depths, the net and its appliances have been constructed somewhat heavier and stronger. Additional weight is secured by passing the tripping arm through a 60 pound shot, of the ordinary pattern used for sounding, the shot being secured by a bolt to prevent its slipping when the arm is capsized. (See Pl. 1, Fig. 4.)

A deep sea tow net, closed, with the folded jaws protecting its mouth, offers little resistance to the water, and can be heaved in rapidly without the danger of being torn away from an open and widespread net ring, while the friction upon the contained organisms is reduced to the minimum.

The time gained in deep sea work, with a folding ring net which will permit of the steam winch reeling in at full speed, and the small stowage space required on shipboard for a net of this pattern, are matters of considerable importance. The readiness with which this net can be carried on deck by one man and attached to the wire dredge rope without complicated adjusting is perhaps the most important point of all in its favor, while its cost is less than that of any intermediate net hitherto employed.

This device has also been constructed in very light form, with a net ring 18 inches in diameter, for use in lakes or at very moderate depths, the heavier outside net being done away with, leaving merely the mosquito netting with its lining of silk bolting cloth.

In this form it will be useful in gathering the minute life, crustacea, etc., of the Great Lakes, a knowledge of which is essential in its bearing upon the food of young whitefish and other important fishes now being propagated artificially.

The folding ring tow net is also available for use as an ordinary surface tow net, without the employment of the messenger and the lead sinker.

The collections made by the Albatross during the past summer with the intermediate net were from depths of 20 to 200 fathoms, the net being lowered in one instance to 575 fathoms, when it accidentally touched bottom. The forms obtained consisted principally of minute crustacea, medusæ, annelids, and fishes, which have not yet been studied; but the ordinary surface tow net having been used at the same stations as the intermediate net, the contents of the two nets were usually found to differ somewhat in character and quantity. As a rule, the surface net contained a slightly greater quantity of material than the intermediate net, but at some stations the reverse was the case, while the intermediate net sometimes brought up forms not taken at all in the surface net. The towings, 18 in all, were made along the border of the submarine bank

* Agassiz, Bull. Mus. Comp. Zool., 1892-93, vol. xxiii, p. 45, etc.

south of the Pribilof Islands during the month of August, from lat. 54° to 56° N. and long. 167° to 172° W. Soundings were from 75 fathoms, on the bank, to 1,901 fathoms beyond it. There can be no doubt that there is an abundance of pelagic life at 200 fathoms in this part of Bering Sea.

After some experience with the single tripping arm described, I designed a machine for opening as well as closing the jaws of the tow net, which worked satisfactorily (Pl. 3). It is a combination of two tripping arms, for operating which two messengers are employed on the same tow line, the second striking a separate detacher from the first. A rough experimental machine, constructed on board the Albatross, was used successfully in port, but did not have strength to withstand the strain of towing at sea. Experiments indicate, however, that a properly constructed machine of the same pattern would accomplish the desired result. Its use in place of the single tripping arm permits of the folding ring tow net being lowered in a closed position, the closing slings being attached to the right arm, the opening slings to the left. The arms are bolted to a bar of brass about 2 feet long, suspended from the tow line, and in position for use are hooked upright to detachers released by messengers. The first messenger tripping the right arm, the jaws of the net fall apart for towing. The second messenger, in turn, tripping the left arm, the weight is thrown back on the slings of the right arm, closing the jaws. A ring-shaped weight around the right slings, and suspended from a hook on the left arm, holds the jaws together for lowering. It is released upon the tripping of the left arm, and slips again to its position upon the right slings, holding the jaws together for heaving in.

The net being closed tightly in going down, it is not necessary to stop the vessel and lower it vertically.

UNDERGROUND PHOTOGRAPHY.*

THE value of photographs in a mining report is evident to everyone, and there are few engineers who have not wished at various times that they could illustrate their papers by means of the camera. I will endeavor to show how, with the simple appliances that can easily be carried into a rough country, photographs can be secured which will much more than repay the slight cost and trouble in taking.

The camera is the most important part of the outfit, and this should be the best obtainable, and in most cases where portability is an object, carrying not larger than a 5 × 7 in. plate. It should be folding, self-containing and, where necessary, focusing by a scale in front, without the aid of the ground glass. The camera should have double swing-backs and sliding front. The tripod, as in surveying, should be adjustable to different heights, and is much steadier by having its legs in only two sections. One should have two lenses, wide angle and rectilinear, for underground and surface work, and these should be able to cover a larger plate than the camera carries, so that the image is sharp when both sliding front and swing backs are used. The best lenses are none too good, as great rapidity is almost always an advantage. The most useful shutter is probably the automatic Bausch & Lomb, with iris diaphragm. I use a 4 × 5 in. folding Kodak, sliding front and double swing-back, Bausch & Lomb lens and shutter. The Poco, Premo, Wizard and some other cameras, when fitted with wide angle lenses, are admirably adapted for underground work, and are very portable.

The plates used should be the quickest possible to obtain. Seeds 27 and Carbutts, also the quick plates of some other makers, work nicely, but little or nothing can be done with a slow plate. Films rarely give complete satisfaction, but where great portability is required cut films seem to work fairly well. The lamp is very important. I have found the "Perfection" lamp (Fig. 2), while not perfection, perhaps the nearest to it of any lamp. The "Perfection" is a magazine lamp, and will serve for from 5 to 15 exposures without refilling. An admirable lamp is made by taking a clay pipe, wiring on to it a lamp wick. The magnesium powder is put in the bowl and the wick, previously soaked in alcohol, is lighted. The magnesium is blown up through the flame by means of a rubber tube or a bulb such as is used with the shutter of the camera. This outfit, costing about 1½ cents, will make as good a picture as the best lamp in the market, but has to be filled each time it is used. This, however, is perhaps an advantage, as it enables the photographer to control the intensity of his flash by the amount of magnesium used, which has to be guessed at with a magazine lamp. Fig. 1 shows the contrivance ready for use.

Blitz-pulver may be used without a lamp, and simply ignited on a rock or shovel. It is easier to regulate the amount of light and much quicker, but it is harder to direct the light and makes more smoke. Magnesium powder with a lamp is, in my opinion, far nicer, less expensive, and in most cases better than blitz-pulver. A box to contain the instruments, plate holders, etc., together with a flask of alcohol for the lamp, is useful. At all events, they should be carried in such a way as to be easily found in obscure light.

In taking the picture it is not necessary to focus very carefully, as the wide angle lens is very nearly universal focus. The best way is to focus with the ground glass on some object about 20 feet away, make some kind of a mark and use this where the light is obscure underground. The camera must be leveled carefully, as the wide angle distorts somewhat, even under the best conditions. This operation is quickened by having a level or a pair of levels on the swing-back. If the swing-back is level, the picture will not be distorted, but the plates must be perpendicular, no matter where the lens is pointing. A ball and socket joint aids in leveling, but makes the camera less steady. By moving candles or lights in front of the camera one can tell exactly how much ground the lens covers and just what the photograph will include. There is rarely enough light to see the image distinctly on the ground glass. Everything being ready, the slide is withdrawn from the plate holder, the shutter opened, unless it was left open in the beginning. The lamp is set going from behind or to one side of the camera a few inches back of the lens. The flash must never get in front of the lens, though candles or lights may be left burning if they are not moved. The exposure lasts according to the size of the workings, and the length of the flash can only be learned by experience. Perhaps three thimblefuls of pure magnesium, or about twice the quantity of blitz-pulver, would light an ordinary sized drift or stope. If the photographer stands behind the camera and causes the lamp to move in an arc from one side over the top to the other, blowing slowly all the while, to throw the light in all directions, the best results can be obtained. A reflector is sometimes useful.

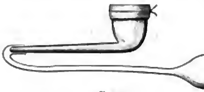

FIG. 1.

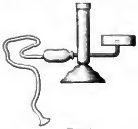

FIG. 2.

Care should be taken not to let the smoke get in front of the camera, as this fogs the picture. This is very difficult in taking low drifts and upraises. In such places it is usually necessary to use blitz-pulver where the plate is exposed and the flash finished before the smoke really gets started. In all cases it is well to study the direction of air currents, both while making the flash and also when a good exposure is desired. I have found it almost impossible to take a second good picture within a reasonable time, even in well ventilated mines. After flashes as well as after blasting, even when the smoke is gone, there seems to remain a practically invisible gas which throws the objects in the picture all on one plane and makes the photograph look like a bass-relief. In taking pictures of shaft houses and mills even in daylight it is often advisable to give one or more flashes to bring out more detail in obscure places. The contrasts otherwise are liable to be too great.

A few words should be added on the subject of developing and printing. Underground flashlights, having so little contrasts, need a good light in developing. They should be developed slowly, and will often be improved by intensifying later on. The author prefers negatives bordering on dense, and thinks that it is difficult if not impossible to over-develop a properly exposed or an under exposed plate. In the boxes with the plates will be found formulas from the makers for developer, intensifying and reducing solutions, and these are usually best suited to the particular brand of plates. Eastman's eikonogen powders and Dr. Anderson's eikonogen cartridges are very useful in traveling. They are cheap, take up little room and do very good work. In developing in tents and the like, starlight or indirect moonlight does little or no harm.

The engineer rarely does his own printing, but he will be rewarded as a rule when he does. Platinum paper gives the best results, as it tones down the sharpness of the ordinary flashlight negative. It is the easiest and quickest paper to handle, though somewhat more expensive than the gelatine papers. Bromide paper, except for very thin negatives, is not as good as platinum, as it is likely to intensify the faults of the negatives. It is admirable, however, for enlargements, and most negatives taken by flashlight can be enlarged with good results.

The accompanying illustrations are reproductions of underground photographs taken in mines in the vicinity of Clear Creek and Idaho Springs in Colorado. They show what can be done with the camera in a mine.

MOISTURE IN COAL.

THE characteristics of different coals with reference to their ability to absorb moisture vary between wide limits. Anthracites are almost wanting in this property. The surfaces of the lumps of anthracite coal become wet when exposed to rain; but there is scarcely any penetration of the moisture into the structure. The semibituminous coals, of which the Cumberland and Pocahontas are examples, absorb some moisture because a considerable portion is usually in the condition of dust; but the part which consists mainly of lumps absorbs little more water into the body of the fuel than does anthracite coal. If a small pile of Cumberland coal which has been wet by the rain is left in the open air, the moisture will quickly and almost wholly disappear after one or two days' drying. The percentage of moisture which these coals contain when subjected to the ordinary exposure of transportation and storage in an unprotected pile seldom reaches as high a point as 5 per cent. The bituminous coals have different properties in this respect. Their power of absorbing moisture is much greater. Some of these coals, which have all the appearance of being practically dry, will, when tested for moisture, shrink 5 per cent. or more. The water enters the structure, and becomes in some degree hydroscopic. The surface indications fail to reveal it. These coals sometimes contain no less than 15 per cent. of moisture, and yet they appear no more moist on the surface than Cumberland coal, which holds but 3 per cent.

It is a matter of some concern how to treat the moisture in the case of wet coal used on an evaporation test. It is agreed that the basis of computation should be the weight of dry coal; but the point at issue is whether the boiler should be given credit for the evaporation of the moisture in the fuel. The subject does not have the importance with the higher grades of coal, because these seldom contain much moisture. As it happens, the coals which contain the large quantities are the ones which are often of the poorest class. With an evaporation, for example, of 5 to 1 and 15 per cent. moisture in the coal, the credit to which the boiler is entitled for evaporating this moisture is 3 per cent.; whereas, in the case of the high grade coals giving, perhaps, 10 to 1 evaporation, with 5 per cent. moisture, the percentage is only one-half of 1 per cent. It would appear, then, that the subject might in some instances be of great importance.

How this should be decided is a question depending upon the object in view. If the commercial value of the coal is the thing desired and the moisture is one of its usual characteristics, then no allowance of any kind should be made for it. The moist condition is the state in which it is purchased, and that is the condition on which the results should be based. If the efficiency of the boiler as a steam generator is desired irrespective of the coal used, it seems certain that the boiler should have the benefit of every advantage to be derived from the use of dry coal, and, under those circumstances, it should have the credit of evaporating the moisture

which the coal contains the same as though moisture was in the interior of the boiler. The boiler should in no respect be made to suffer because of the heat lost in this way.—Engineering Record, U. S. A.

ALUMINUM IN KNITTING MACHINERY.*

By GEORGE D. RICE.

FIVE years ago the price of aluminum was $3 per pound. Now it can be purchased for 50 cents per pound. With the reduction in price has come a gradual employment of the metal in all lines of machine work.

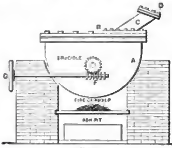

Fig. 1

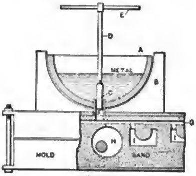

Fig. 2.

The writer has interviewed knitting machine builders who have experimented with aluminum and aluminum bronze castings in parts of knitting machinery that require great strength, and other builders who are contemplating work on this line.

As the processes of treating and casting aluminum for knitting machinery parts are quite new, the accompanying illustrated description may be useful to those knitting machine builders who wish to try the new metal. Aluminum castings can be bought at the foundries from 45 cents per pound and upward. The price for aluminum hardened with other alloying metals is a few cents higher per pound. The tensile strength of the hardened metal averages 21,000 pounds per square inch, thus making it well adapted to many small parts of the knitting machine. Tests have demonstrated that the shrinkage of aluminum is about one-quarter of an inch in a twelve-inch sample.

* From Machinery.

Although advisable to buy the aluminum crude castings already hardened, the purchaser may increase the hardness by adding zinc, manganese, tin, brass, nickel or other like metals. Aluminized zinc brass makes a most durable metal for knitting machine needle cams.

PROCESS OF MAKING ALUMINUM CASTINGS FOR KNITTING MACHINERY.

Electrical machinery builders are now using this metal in places where strength is needed. For general purposes, however, a good alloy from which to make cams, bearing sleeves, small castings and the like for knitting machinery may be made as follows:

Aluminum	95·00
Antimony	3·04
Tin	0·96
Copper	0·94
Tungsten	0·06
Total	100·00

The tensile strength of parts made from this alloy is 25,000 lb. It can be cast in sand moulds. The melting and casting of aluminum alloys into knitting machinery parts requires an equipment something like that shown in the diagrams, the first of which is a sectional view of the melting pot or crucible, A, which is set up in a brick affair over a coke fire. Coke must be used, and

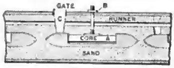

Fig. 3

Fig. 4

Fig. 5

Fig. 6

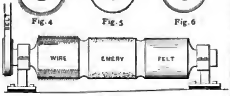

Fig. 7

not coal, as the gases from the latter are liable to impregnate the metal. The crucible can be balanced on a shaft, on which shaft should be keyed a gear. A worm shaft can be arranged to engage with the cogs as shown at F, and by turning this shaft with a handle at G, the crucible can be poured. The lid, B, is provided with a spout, C, the end of which can be closed with the cap, D. The latter is, of course, removed when the metal is poured. Next the ladle should be erected, as shown in section in Fig. 2, in which the ladle itself is marked A, and the pouring gate channel, F. This gate is stopped with the plug, C, and the latter raised and depressed by means of the shaft, D, and handle bar, E. By this arrangement the metal is poured from the bottom and scum is avoided. The arrangement of the mould does not differ enough from ordinary descriptions to call for detailed account.

The gate channel leads into the runner, G, and the metal flows through to the moulds, H and I. Perhaps in this connection it may be well to refer to the method of casting aluminum shuttles. The mould box is shown in sectional view in Fig. 3, and the gate for pouring is at C, where it branches off into the runner, and several shuttle moulds are connected with it. The core of the hollow of the shuttle is indicated at A, consisting of a correctly shaped metallic piece, wound with hemp and swept with loam. It is held in place by the stem, B. After the castings are taken from the moulds, the finishing processes call for the usual chipping, cleaning and smoothing. Some special wheels are used in the work, and these are shown in the next sketches, that in Fig. 4 being a side view of a "scratch" wheel made by covering a wood cylinder with medium sized fancy clothing wire. The use of this wheel is to remove fins, etc., from the castings. The next wheel (5) is covered with fine emery, for evening off the surfaces, and the last wheel (Fig. 6) is for buffing purposes, being covered with felt or pile fabric.

These wheels may be set up separately in stands of wood and revolved by belts, or all may be arranged on one cylinder with a division between each, as shown in Fig. 7.

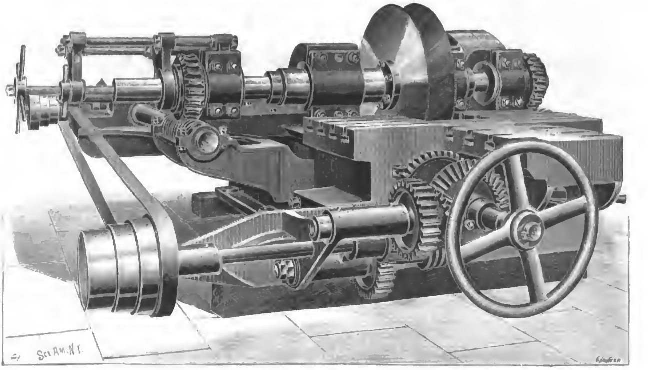
If the castings should prove too brittle, anneal them by heating to cherry red and dipping in cold water. Three points are claimed for the aluminum hollow castings. They are lighter, tougher and look better than iron or steel castings. On the other hand, they cost more, but not much more than iron or steel parts. Concerning looks, this is quite an item in these days, and if the aluminum alloy castings are given the so-called nickel polish, a very attractive machine is made. This nickel polish is easily and cheaply applied, consisting in buffing the surfaces of the castings or other aluminum parts, and putting on nickel rouge or crocus composition. The buffing is done in this case with soft muslin or loose cotton wheels. A shiny nickel-like polish results and sets off the knitting machine to advantage.

A RAPID METHOD FOR THE DETERMINATION OF SILICON IN SILICO-SPIEGEL AND FERRO-SILICON.

C. B. MURRAY and G. P. Maury, in the Journal of the American Chemical Society, 1897, 19, 138, 139, describe the following method: 0·5 gr. of the sample is placed in a porcelain or platinum dish; 30 c. c. of water, 10 c. c. of hydrochloric acid (sp. gr. 1·20), and 12 c. c. of sulphuric acid (one part of sulphuric acid [1·84 sp. gr.] to three parts of water) are poured on it, and the contents of the dish heated until copious fumes of sulphuric acid are given off. When cool, 10 c. c. of hydrochloric acid are added, and the whole is heated to soften the sulphate of iron; finally it is treated with 75 c. c. of water, and raised to boiling. The heating is discontinued, and note taken as to whether there is any effervescence when boiling ceases. Should this occur, the liquid must be evaporated until copious fumes of sulphuric acid are again given off, and then it is treated in the manner above described. The solution is filtered, washed with hydrochloric acid and hot water, ignited in a platinum crucible, and weighed. A few drops of sulphuric acid and enough hydrofluoric acid are added to dissolve the silica. The liquid is then evaporated to dryness, heated to decompose the sulphates, cooled and weighed. The difference in the two weights represents silica. The whole operation can be accomplished in thirty minutes.

COLD SAW FOR CRANK WEBS.

THE accompanying engraving illustrates a heavy cold saw just constructed for a Midland firm by Messrs. Hill & Sons, St. George's Works, Derby. It is specially intended for sawing out crank webs. Each saw is fitted with the makers' patent flush sides. One is stationary, the other is movable to suit the traverse of the telescopic saw spindle. The engraving is self-explanatory.—The Engineer.



SAW FOR CRANK WEBS.

[Continued from Supplement, No. 1130, page 18059.]

PERPETUAL MOTION.—II.*

The two self-movers, which it has been claimed were really such, were the inventions of the Marquis of Worcester, author of the "Century of Inventions," and Jean Ernest Elie Bessler Orffyré, or Orphyreus, who is usually named Orffyreus in English and German works. The latter was born in 1680 near Zittau, in the department of Alsace, France, and early studied theology and medicine, but his erratic genius was only to be satisfied by engaging himself in the pursuit of a variety of the mechanical arts and painting. He asserts that it was during his search for whatever might prove curious and valuable that he discovered perpetual motion, and between the years 1712 and 1719 made two machines on his system; one he desired to exhibit publicly, but broke it up rather than submit to the payment of the license or tax required by the government of Cassel; the other he destroyed after its having been unfavorably reported on by M. 'S Gravesande. He published in German and Latin a book or pamphlet entitled "Le Mouvement Perpétuel Triomphant," quarto, dated Cassel, 1719. Other accounts differ respecting the breaking of the second machine, and, on insufficient authority, Mr. Partington styles him a "German mechanic." Dr. William Kenrick, among his miscellaneous works, wrote "An Account of the Automaton or Perpetual Motion of Orffyreus, with additional remarks," in editions dated 1770 and 1771. Orffyreus died in November, 1745.

The following is a description of the Marquis of Worcester's wheel, described in the 56th article of the "Century of Inventions" as "An Advantageous Change of Centers."

"To provide and make that all ye weights of ye descending syde of a wheele shal be perpetually further from ye center, then those of ye mounting syde, and yett equal in number and heft of ye one syde as ye other. A most incredible thing if not seene, butt tryed before ye late King of happy and glorious memorye in ye Tower by my directions, two Extraordinary Embassadors accompanying his Matie and ye D. of Richmond, D. Hamilton, and most part of ye Court attending him. The wheele was 14 foote over, and 40 weights of 50 pd apiece; S Wm. Belford, then Lieut of ye Tower, and yet living can justify it with severall others; they all saw that noe sooner these great weights passed ye Diameter Line of ye vpper syde but they hung a foote further from ye center, nor no sooner passed the Diameter line of the lower syde, butt they hung a foote nearer; bee pleased to judge ye consequence."

Of the inventions of these two men Dircks says:

"The only appeal that can be made in apology for the pursuit of perpetual motion is derivable from the results represented to have been obtained by the Marquis of Worcester in one instance and by Orffyreus in another. All the circumstances relating to their singular inventions excite our curiosity, raise our skepticism and induce us to pause in our decision. Let us first consider the inventors personally; and, secondly, their inventions and the circumstances attending their exhibition. The two men were of very different character and position in life. The first noble by birth, of ancient lineage, loyal to the extent of sacrificing his property in support of the cause of Charles I, and evidencing by his prayers his truly religious sentiments. About or before 1648 (as the King died 1649), he exhibited his wheel or perpetual motion in the Tower before his Majesty, two extraordinary ambassadors, the Duke of Richmond, Duke Hamilton, most part of the Court and Sir William Belford, Lord Lieutenant of the Tower. We have to consider the upright character of the Marquis, his having invented the steam engine, his worthiness in all respects and the circumstances here detailed, and then ask ourselves: Little as science favors any belief in such an invention, can we see any reasonable grounds for error in this great experiment, or believe that a person so distinguished and so much to be admired in all other respects could thus boldly and recklessly deceive himself, his noble company and the public, taking ten years or upward to elaborate and record a gross falsehood? It seems incredible, and true respect for the marquis' memory will go far to maintain doubts respecting the infallibility of all mathematical demonstrations adverse to the possibility of a self-motive power. Secondly:

"Orffyreus was of humble origin, had versatile talents, and fickle, discontented, unsettled, irregular, and eccentric. He was ambitious, boasting and the very man to raise up enemies. Between 1712 and 1718 he made and destroyed in succession four wheels or machines. He had learned the art of clock making and several mechanical arts, and is supposed to have constructed or put these wheels together himself. He had a princely patron who wished to obtain practical results from the invention for manufacturing and other operations. A misunderstanding ensues; and from that time to his death, in 1745—at least twenty-eight years—the subject lies dormant and the invention dies with him. This last fact, coupled with the wheel having raised so great a weight as 70 pounds, makes a doubtful case still more doubtful; and particularly when, about the same time, Geiser imposed on the German public with a mere piece of clockwork as a true perpetual motion.

"The Marquis of Worcester's wheel was 14 feet in diameter; it was rotated by the action of forty 50 pound weights—2,000 pounds—an enormous weight, requiring some very laborious operations of the carpenter to erect a sufficiently strong framework. Its completion must have taken some time and led to frequent visits from the noble inventor, as well as experiments to test its correct working before offering a practical demonstration before majesty.

"Orffyreus' fourth or last wheel, at Hesse Cassel, was 12 feet in diameter, 14 inches broad and made of light oak framing and covered with oil cloth. It would revolve either way, and this alone casts a shade of doubt on there being any deception in practice with it. But, strange to say, it had power enough to raise 70 pounds to a considerable height. Its operations were seen and attested by so many that these broad facts rest not alone on the inventor's authority. It was so ingeniously made that M. Gravesande wrote to Sir Isaac Newton on the subject; and his letter and mathematical reasonings in reference to the matter appear in his works, edited by Prof. Lalande, 1774."

* Reprinted from the Scientific American, 1870-71.

The following is the letter written by Prof. S. Gravesande to Sir Isaac Newton in regard to the wheel of Orffyreus:

Sir: Dr. Desaguliers has doubtless shown you the letter that Baron Fischer wrote to him some time ago about the wheel of Orffyreus, which the inventor affirms to be a perpetual motion. The landgrave, who is a lover of the sciences and fine arts, and neglects no opportunity to encourage the several discoveries and improvements that are presented him, was desirous of having this machine made known to the world for the sake of public utility. To this end he engaged me to examine it; wishing that, if it should be found to answer the pretensions of the inventor, it might be made known to persons of greater abilities, who might deduce from it those services which are naturally to be expected from so singular an invention. You will not be displeased, I presume, with a circumstantial account of this examination. I transmit you, therefore, a detail of the most particular circumstances observable on an exterior view of a machine, concerning which the sentiments of most people are greatly divided, while almost all the mathematicians are against it. The majority maintain the impossibility of a perpetual motion, and hence it is that so little attention hath been paid to Orffyreus and his invention.

Fig. 5.

For my part, however, though I confess my abilities inferior to those of many who have given their demonstrations of this impossibility, yet I will communicate to you the real sentiments with which I entered on the examination of this machine. It is now more than seven years since I conceived I discovered the paralogism of those demonstrations, in that, though true in themselves, they were not applicable to all possible machines, and have ever since remained perfectly persuaded it might be demonstrated that a perpetual motion involved no contradiction; it appearing to me that Leibnitz was wrong in laying down the impossibility of the perpetual motion as an axiom. Notwithstanding this persuasion, however, I was far from believing Orffyreus capable of making such a discovery, looking upon it as an invention not to be made (if ever) till after many other previous discoveries. But since I have examined the machine, it is impossible for me to express my surprise.

The inventor has a turn for mechanics, but is far from being a profound mathematician, and yet his machine hath something in it prodigiously astonishing, even though it should be an imposition. The following is a description of the external parts of the machine, the inside of which the inventor will not permit to be seen, lest any one should rob him of his secret. It is a hollow wheel or kind of drum about 14 inches thick and 12 feet diameter, being very light, as it consists of several cross pieces of wood framed together, the whole of which is covered over with canvas to prevent the inside from being seen. Through the center of this wheel or drum runs an axis of about six inches diameter, terminated at both ends by iron axes of about three quarters of an inch diameter upon which the machine turns. I have examined these axes, and am firmly persuaded that nothing from without the wheel in the least contributes to its motion. When I turned it but gently, it always stood still as soon as I took away my hand; but when I gave it any tolerable degree of velocity, I was always obliged to stop it again by force; for when I let it go, it acquired in two or three turns its greatest velocity, after which it revolved for twenty-five or twenty-six times a minute. This motion it preserved some time ago for two months in an apartment of the castle, the doors and windows of which were locked and sealed, so that there was no possibility of fraud. At the expiration of that term indeed his serene highness ordered the apartment to be opened and the machine to be stopped, lest, as it was only a model, the parts might suffer by so much agitation. The landgrave being himself present on my examination of this machine, I took the liberty to ask him, as he had seen the inside of it, whether, after being in motion for a certain time, no alteration was made in the component parts; or whether none of those parts might be suspected of concealing some fraud; on which his serene highness assured me to the contrary, and that the machine was very simple.

You see, sir, I have not had any absolute demonstration that the principle of motion, which is certainly within the wheel, is really a principle of perpetual motion; but at the same time it cannot be denied that I have received very good reasons to think so, which is a strong presumption in favor of the inventor. The landgrave hath made Orffyreus a very handsome present to be let into the secret of the machine, under an engagement, nevertheless, not to discover or to make any use of it before the inventor may procure a sufficient reward for making his discovery public.

I am very sensible, sir, that it is in England only the arts and sciences are so generally cultivated as to afford any prospect of the inventor's acquiring a reward adequate to this discovery. He requires nothing more than the assurance of having it paid him in case his machine is found to be really a perpetual motion; and as he desires nothing more than this assurance till the construction of the machine be displayed and fairly examined, it cannot be expected he should submit to such examination before such assurance be given him. Now, sir, as it would conduce to public utility, as well as to the advancement of science, to discover the reality or the fraud of this invention, I conceive the relation of the above circumstances could not fail of being acceptable.

Partington, in his "Manual of Natural Philosophy," endeavors to interpret the somewhat enigmatical specification of the Marquis of Worcester by the accompanying diagram, Fig. 5, which it is self-evident almost at a glance can have no movement except that derived from external forces.

Making a long jump from the remote to the near, we shall next present an illustration of a perpetual motion machine invented by Horace Wickham, Jr., of Chicago, Ill., and on which a patent was obtained July 20, 1870. Mr. Wickham will thank us for placing him in such honorable company as the Marquis of Worcester, and our readers will perhaps be glad to see the form and essence of a machine which Western journals have greatly lauded as most wonderfully ingenious, etc., though if they can see how it generates any motive power, their mental vision will be superior to ours.

A is the bed or table upon which the standards for supporting different parts of the machine are secured. B B are the standards for supporting rocking beam, C. This rocking beam is pivoted at the center to the standards by the ring, D, and set screws. These centers have points like lathe centers. The other parts of the machine consist of a governor, fly wheel, etc.

C is the rocking beam, constructed in two parts and secured together by the bands, E. The rocking beam consists of two tubes; the upper one is made straight and the lower one in the form of a W. These tubes are connected together at their ends in such a manner as to allow the ball used to pass from the lower tube to the upper one by means of hinged inclined runways, F, and valve, G, and from the upper one to the lower, inside of the band, E, by the opening therein. The inclined runway, C, is hinged at one end to the upper tube, F, at the bottom of its opening or exit, made of the band, E, while the other end rests on the valve, G.

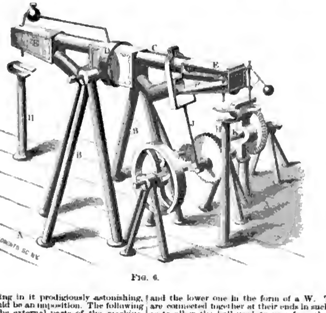


Fig. 6.

This valve has attached on its under side a pin which projects down through a hole in the band, E, a sufficient distance, so that, when the pin strikes the standard, H, secured to the bed or table, as the rocking beam oscillates it will raise the valve a short distance above the upper tube. The valve is made to incline toward the opening in the upper tube, so that the ball, when raised on the valve, will roll into the same, by means of the hinged inclined runway, F. I is a ball which runs in the upper and lower tubes; this ball is charged with a necessary amount of quicksilver, for giving more weight to the same, and also for giving a much quicker momentum to the ball. This

ball is to be used in the rocking beam for the purpose of unbalancing, and also to exert the pressure of its specific gravity on the same at whatever point or position it may be in, and in so doing it assists in oscillating it.

The pitman, J, connects the crank shaft with the oscillating beam. The rocking beam is provided, on the opposite end to which the pitman is attached, with a rod, on which is placed an adjustable weight, which is secured at any desired point by means of a set screw. This weight is for the purpose of counterbalancing the adjustable band provided with a rod to which the pitman is attached, and also the pitman. The governor is for the purpose of regulating the motion of the

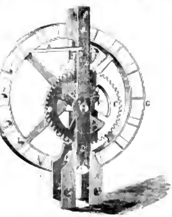

FIG. 7.

machine, and is operated through the medium of a gear wheel on the crank shaft, and other suitable gearing. The governor is constructed in the usual manner, excepting in using the cutoff valve, as in steam engines, which is dispensed with, and an automatic brake is used and operated by means of the rise and fall of the governor balls. The automatic brake consists of an elastic band, one end of which passes up through a hole in the guide rod projecting from the standard that supports the governor, and is connected to an arm projecting toward and partly around the upright shaft of the governor.

The tension of the band is regulated by nuts and screw-thread on the end of the band. The other end of the band passes under a wheel on the shaft, K, and is secured to a projecting arm on the standard that supports the governor. The crank shaft is counterbalanced.

I do not wish to confine myself to the precise construction of the rocking beam, as shown and described, as I intend using, in lieu thereof, wires, or rods, arranged in the form and shape of the rocking beam described, with mounted weights arranged to roll on them, which, in connection with the other parts of the machine, will accomplish the same result.

The lower tube can be made semicircular in form and shape instead of the form and shape of a W. Any number of rocking beams may be used, and more than one ball can be used in the rocking beam, by having inclined runways and valves on each end of said beam; the rocking beam so arranged that the balls drop from one tube to the other at the center of the beam, and rolling alternately from the center to the ends of the beam.

The rocking beam is oscillated by any power operating alternately on each end of the same, and which transmits motion to the other parts of the machine through the medium of the pitman and crank shaft, and for applying power to any other machine a pitman is secured on the opposite side of the rocking beam to which the pitman, J, is attached, or, instead thereof, pulleys, and endless belts on the shaft, K, or the crank shaft.

The spokes of the fly wheel are charged with quicksilver, for the purpose of giving weight to the same at any desired point, as it passes from the center to the circumfer[illegible] of the wheel.

It is claimed that this machine has run seven months without stopping, independent of any external force, which we do not believe, and we think our readers, after reading the above description of it, abstracted from the specification on file in the Patent Office, will concur with us in our belief.

In 1790, one Conradus Schwiers, a doctor of divinity, patented a "machine on a self-moving principle, or perpetual motion." Fig. 7 is a view of this machine, which, it will be at once seen, is an effort, since often repeated, to obtain a wheel so as to keep its center of gravity from ever falling directly under the axis while revolving. The following is the specification:

"Now know ye, that in obedience of the said letters patent, and the proviso therein contained, I, the said Conradus Schwiers, do hereby declare my said new invented self-moving principle, or perpetual motion, is made and performed in manner following, that is to say:

"Two stiles or uprights marked in the plan hereunto annexed, A, A, etc., and fastened together by the screws, 1, 2, 3, and to the base, between which stiles or uprights run the wheel, C, and the pinion, D, and the two double pinions, D, D, etc., over which double pinions run a double chain, etc., to which chain are fixed the buckets, F, F, etc. The chain is made with joints on each side and bars running across, equal in number to the cogs of the wheel, C. Upon the same axle with the wheel, C, on the farther side of the inner stile, A, runs the wheel, G, whose diameter is full double that of the wheel, C; and the pivot of the wheel, G, runs in the buck, H, as the other pivot of the same axle runs in the front stile, A. The wheel, G, is divided near the periphery into receptacles in number equal to the buckets on the chain, which receptacles are supplied with metal balls, I, I, etc., from the buckets, F, F, etc., by means of the gutter, K, which balls by their weight forcing round the wheel, G, and thereby lifting up the buckets, F, F, etc., on one side as they go down on the other side, discharge themselves again at the bucket, L, where they are taken up by the buckets, F, F, etc., and discharged again at the gutter, K, and are so repeated in a constant succession as often as any receptacle is vacant in the wheel, G, at the gutter, K, for their reception, and by that means the perpetual revolution is obtained, the upper ball being at the same time discharged from one bucket when the lower ball is taken up by another." A very common principle has been worked out to uniform failure in various ways, from the earliest to the latest times. It is shown in the accompanying diagram, Fig. 8, which represents a large wheel, the circumference of which is furnished, at equal distances, with levers, each bearing at its extremity a weight, and movable on a hinge, so that in one direction they can rest upon the circumference, while on the opposite side, being carried away by the weight at the extremity, they are obliged to arrange themselves in the direction of the radius continued. This being supposed, it is evident that when the wheel turns in the direction, a, b, c, the weights, A, B, and C, will recede from the center; consequently, as they act with more force, they will carry the wheel toward that side; and as a new lever will be thrown out, in proportion as the wheel revolves, it thence follows, say they, that the wheel will continue to move in the same direction. But, notwithstanding the specious appearance of this reasoning, experience has proved that the machine will not go; and it may indeed be demonstrated that there is a certain position in which the center of gravity of all these weights is in the vertical plane passing through the point of suspension, and that therefore it must stop.

Fit companions to these remarkable specimens of false reasoning are the two modern devices of which we give illustrations in Figs. 9 and 10.

Fig. 9 represents a device by Charles Batcheller, of Polk County, Iowa, on which he took out a patent during 1870.

"My invention is designed to provide a simple balance power, that may be advantageously used in connection with any machinery where a balance wheel or fly wheel is used or may be used. By my combination of levers, weights and gearing, I create a compound power that is perfectly balanced when at rest. Thus far it is similar to a common fly wheel. But less force is required to put my compound wheel in motion, and, after being started, it accumulates a greater power, and much more rapidly, than an ordinary balance wheel. The degree of power actually gained has not been accurately determined. In addition to the increase of power I gain an increase of speed. While my compound balance lever power makes one revolution, the inside shafts and wheels thereto attached make two revolutions. The illustration is a perspective view of my compound balance lever mounted on a frame. A is the frame. B represents pieces forming frames, in each of which are hung three geared wheels. There are two of these frames and two sets of these geared wheels. C is a geared wheel, which can be used for communicating power. D, belt wheels, which are also used to communicate power. These can be used at the same time, one on each side; and in place of the belt wheels and belting, geared wheels may be substituted. E represents weighted levers firmly secured to the axes of the geared wheels. There are four of these weighted levers, but only three shown in the illustration. G represents geared wheels secured on the hollow shafts, H, together with the frames, B. There are two of the geared wheels, and they are so placed that they connect the two sets of wheels and weights. By this connection the balancing power is formed. The frames, B, and the wheels, G,

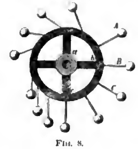

FIG. 8.

are secured upon the hollow shafts, so that they cannot move independent of each other. Shafts are placed within the hollow shafts, H, upon which the communicating wheels, D, and the center wheels are secured, so that they can move independent of the frames, B, and wheels, G. While the frames, B, make one revolution, the wheels, D, and the center wheels, make two revolutions. This is caused by the action of the weighted levers, E. Their weight, or inertia, prevents them from passing around the center of the axis of the wheels with which they are suspended in the revolving frames. The full force of this resistance, or inertia, is applied to the other wheels of each set, and by these wheels communicated to the center wheel.

"The size and weight of this compound balance lever power may be varied and adapted to the various uses to which it may be applied."

Fig. 10 is a device of Doctor Alois Drasch, of St. Egidi, Austria, patented in the United States, December 22, 1868.

"This invention consists in the arrangement of an annular tilting tray, which forms the orbit for a revolving ball, in combination with a supporting platform, and with a lever which extends into the tray and connects with a shaft, to which motion is to be imparted, in such a manner that, by continually changing the position of the tray, the ball is caused to rotate therein without interruption, and by the action of the rotating ball on the lever the desired motion is imparted to the shaft, which connects with the working machines or mechanism to be driven. A represents a tray, which forms an annular path, or orbit, for the ball, B. This tray is made of sheet metal, or any other suitable material, and its diameter is about four times that of the ball, B. It is supported in its center by a rod, which connects, by a ball and socket joint, C, with a platform, D, so that said tray can be readily tilted in any desired direction. From the edge of the platform, D, rises a circular rim, E, which prevents the tray from being tilted any lower than desirable. The position of the tray is governed by a hand lever, F, which enables the operator to con-

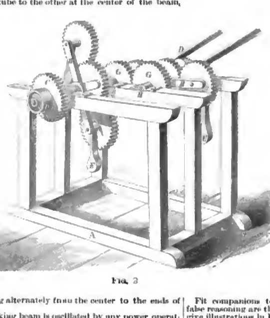

FIG. 3

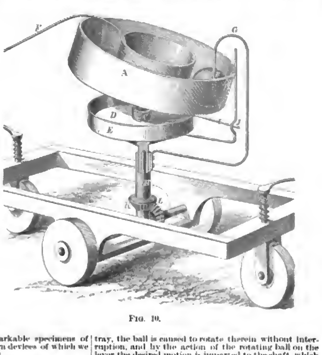

FIG. 10.

tinually tilt said tray in advance of the rotating ball, so that said ball is kept rolling on a continually changing inclined plane; and, as the ball progresses in its orbit, it bears on a lever, G, which extends from the shaft, H, into the tray, as shown in the drawing. The tray is guided in its tilting motion by an arm, I, which is firmly attached to its circumference, and catches in a loop, J, secured to the edge of the platform, D. The shaft, H, is intended to transmit the motion, imparted to it by the action of the ball, B, to the working machines, or to a mechanism of any desired construction.

"In the drawing, my motor is shown as applied for propelling a railroad car, or vehicle, and in this case the shaft, H, bears a bevel wheel, K, which gears into a similar bevel wheel, L, mounted on the axle of the car, or vehicle, so that the rotary motion imparted to the shaft, F, will be transmitted to the axle of the car, or vehicle, and the desired motion of said car, or vehicle, will be effected. It is obvious, however, that my rotary ball motor is applicable for the purpose of driving machinery of any kind, and it is particularly valuable in localities where the erection of a steam engine, or other motor, would be difficult or impracticable."

(To be continued.)

THE STOCKHOLM EXHIBITION.

A SPECIAL charm has been added the past summer to the many attractions of the beautiful Swedish capital Stockholm. In close proximity to the town, bounded on one side by the wooded slopes of the zoological garden, on the other by the extended cliffs of the Baltic, an exhibition of productions of the North spreads gay life around. But not only by its beautiful site is the exhibition distinguished. It is marked by a general excellence in the artistic and clever arrangement of its rich and interesting array of exhibits. It brings before our eyes the commerce and industry, the social life and the educational progress of a hard working people, a people which, notwithstanding its modesty, is fully conscious of its own power, and which at this exhibition proves to the world that intelligence and carefully trained talent place it on a par with the other civilized nations in the great strife of culture and industry.

Another merit of this exhibition is its freedom from those worthless shows, calculated to satisfy the tastes of a mixed public, which have lately infested many of the over-numerous exhibitions opened throughout Europe. The Stockholm exhibition has a dignified reserve which was well in keeping with the refined, industrious, national character of the Swede.

Much of the success was due to the assiduous efforts of the Crown Prince, who, as patron, not merely nominally but actively supported the enterprise. Wherever a difficulty arose his helping hand was felt, and he again found a ready counselor and supporter in his father, King Oscar II. The younger prince, too, Gustavus, himself a talented painter, paid much attention to the management of the art department of the exhibition. With such influential personages exerting all in their power toward the successful development of the undertaking, this rapidly grew in extent to an unexpected size, Denmark and Russia competing with additional zeal. When, therefore, in May, King Oscar opened the exhibition with an appropriate speech, his words were greeted with shouts of joy and cheers of applause, in honor of the Stockholm Exhibition, a completed and wonderful work, filling all with admiration for the good taste and the zeal of its promoters.

OLD STOCKHOLM.

The great variety by which this exhibition was marked shows itself already in the exterior of the buildings. These, extending over 3,900,000 square feet, differ greatly in style, all buildings being represented, from the massive Gothic and the graceful rococo to the pretty Norse wood cottages, with colored façades, harmonizing most perfectly with the picturesque surroundings.

Immediately upon entering by the main gate we are confronted by a contrast. On the right we have the somber brick built northern museum, and in front is the great central palace, raised of wood only, in charming variety, crowned with a many colored cupola,

INDUSTRIAL AND ART EXHIBITION, STOCKHOLM, SWEDEN.

which is connected to four graceful minarets by slender bridges. The whole with its delicate façade reminds us of a Hindoo temple. To these minarets elevators raise the visitors, who from the height may enjoy a view over the whole exhibition grounds, and over the grand scenery of woods and waters around, which surround the beautiful city of Stockholm, with its grand palaces and churches, its ever busy streets and squares. In the rooms of the northern museum we find departments for education, instruction, science, hygiene and domestic industry, which last finds special support and stimulus from the Swedish government.

In this department we see real wonders in woman's work: the most beautiful embroidery, often with ancient Swedish designs, painted wood carving of exquisite shape, woven carpets and curtains, lace and allied work, even furniture in peculiar shapes and colors. The work of children, too, deserves our attention, for the elder workers would never have attained their perfection, had they not learned early to use their tools and material.

The central palace holds the industrial productions of Scandinavia, Denmark, and Russia. Here, too, our interest is fanned by the great variety, for the different realms have each separate industries, of which they represent their greatest and best at this exhibition. Thus Sweden shows artistic gold, silver and steel work, besides beautiful porcelain, which equals the Danish china in its peculiar coloration and its polish. Sweden also exhibits costly furs, fine marble and granite. Norway has first wood industry, then also metal work finished with extreme care, while in Russia's array we find bronzes and enamels. These are, of course, but a few of the numberless exhibits. Norway, of course, gave special attention to the late Nansen expedition, a model of the Fram, some remaining provisions, showing that the men were not hard pressed by hunger, a few weapons and some hunting trophies of the daring explorer, such as polar bears, skins, etc., also relics, as his sealskin jacket, and his small boat and sledge, are there to remind us of his adventurous and fortunate journey north. Two of his faithful dogs, that followed him, are here to be seen stuffed.

Near these two buildings, the northern museum and the central palace, are a number of pretty pavilions, serving for various special exhibitions and for entertainments of an instructive character. Thus there is a pavilion for sport and touring, including artistic panoramas, the most exhaustive outfits for traveling, mountaineering, glacier climbing and snowshoeing, for land and water sports of every kind. Then a pavilion for chemical industries, the pavilion of the city of Stockholm, built in rococo style, and holding all that is interesting in the public and social organization of the town; very practical are the school and the ambulance arrangements, worthy of imitation the courses in housekeeping, etc., for young girls. The underground arrangement of sewers, gas mains, etc., is made plain by a vertical section reproduced in full size. With its wood carved façade turned toward the water stands the building of the Swedish-Danish fisheries. It is built in brown wood; its exhibits offer much that is of interest and novelty even to the initiated. The models of crafts serving partly for passenger and freight transport, partly for fishing, are a great attraction. To this building is attached another devoted to Norwegian fisheries, and showing of what importance this trade is to the nation. The outfits for whaling and hunting the seal are here the features of chief interest. The riches of the Swedish forests are gathered together in a pavilion, of which the log walls and moss covered roof are sufficient indication as regards its contents. Here, too, a fine panorama supplements the well arranged collection, as also in the biological museum close by, which has been located in a quaint old peasant's cottage. This in itself is quite a curiosity. In it we see the great variety of animals found in Scandinavia represented by exquisitely stuffed specimens. Then, rising upon a neighboring hill, stands the pavilion of the Royal Hunting Club, whose president is the Crown Prince, and by whose members a considerable portion of the exhibits were secured. A little farther we come to the shining white exhibition of Swedish music and drama, with many historical memorials and a large concert hall. Here the compositions of the most eminent of Swedish masters of this century are rendered by first class musicians.

Along the banks of the Djurgarden-Vaken old Stockholm extends with its walls and turrets, its ramparts and ditches, defended by a number of quaintly shaped weapons, erstwhile perilous to the enemy, and guarded by martial looking lansquenets in the becoming uniform of the days of Gustavus Adolphus. This model of ancient Stockholm, with its narrow, crooked streets, full of antique houses, with workshops and inns, a church and the city hall, is one of the most perfect productions of its kind ever seen. In none of the representations of old towns used at exhibitions upon so many occasions within the last decade was the visitor so impressed by a feeling of reality as here. Not only is the whole construction kept very true to nature and history, but the gable houses are built of solid material, and touch us with a homely feeling, calling to memory the days of long ago. Close to the water, on a large scale, is built the old royal castle, the "Tre Kroner." Within its castle yard it is easy to fancy one's self back to past centuries, for everything here is in wonderful harmony, making one forget the present: the surrounding ramparts, with their narrow drawbridges, the castle yard with its low outlets to prison den like vaults, the staircases to the inner halls and chambers, and, lastly, the view from the porch over the market place, which in days gone by resounded on many an occasion with the clash of arms and the battle cry.

To-day peace reigns over the land. Sweden, once the home of such great warriors as Gustavus Adolphus, is now friendly to the neighboring states. But that it is able in the case of need to make a stand for liberty we are convinced when we visit the white palace of the navy and army department. This stands in the second western part of the exhibition, and the strength of Sweden by land and by water is here clearly demonstrated. We are made acquainted with the internal organization of the army and navy, and we are shown what a stress is laid by the government on the mental and physical development of the people. In lifelike groups the various army divisions are placed before us. The uniforms are becoming and practical, the officers and soldiers are marked by their modest bearing. The artillery is represented in particular completeness, partly here and partly in the pavilion for iron and steel industry. By models the rapid development of the Swedish navy is graphically demonstrated.

From the very water's edge extends the great machinery hall, built solely of glass and iron, and behind it, on a higher level, the white building of the art gallery, where nearly all nations of Europe were represented. But one of the most interesting exhibits is stationed close by, the great steel-built steamer Södra Sverige, which sank in the "Schären" (cliffs), in 1895, on the journey to St. Petersburg, and lay for nearly two years at a depth of some two hundred feet, to be raised to the surface again quite lately by an ingenious device, the invention of the engineer Waller, and to be brought to the exhibition by steam. When the boat, which is worth some $125,000, has undergone some further repair, it will again be quite seaworthy. One more item must be mentioned before we close our account of this exhibition—that is the Skansen, a thing unique in its kind, a national museum in openair. Overshadowed by gigantic northern trees, there are collected here a number of peasant cottages, which have been transported hither with inhabitants and all their domestic utensils and furniture from the various parts of the land, giving us a perfectly true picture of Swedish country life. The Skansen was founded by Prof. Hazelius at the beginning of this decade, and has since prospered, increasing visibly from year to year, owing to vivid interest taken in its welfare.

The exhibition was held in honor of the twenty-fifth anniversary of the present king's coronation. No better or more worthy gift could the nation have brought its ruler, for by it is shown the progress in all branches of industry which has attended the peaceful reign of the monarch, and no mean compliment is thus paid with great delicacy to King Oscar II, of Sweden.

The illustrations accompanying our article are from Ueber Land und Meer.

THE NEW RUSSIAN CHURCH IN KARLSBAD.

THE NEW RUSSIAN CHURCH AT KARLSBAD, BOHEMIA.

A FEW weeks ago Karlsbad saw the inauguration of a Greek Catholic church. The new building does not only fill a long felt want in that much frequented summer resort, but it also figures highly among the great architectural sights of the city. The erection of a Greek Catholic church for the use of the Russian guests had long been contemplated. In 1866 Washington House, a building in the Marienbaderstrasse, was purchased, and by the work of the architect Mayblum transformed into a hall for religious services. But soon its capacity was found insufficient for the growing number of visitors. A piece of land on the Parkstrasse was bought as a site for a new church, the funds being partly presented by Russian guests who had sought and found health at Karlsbad, and partly granted by the Russian ministry, and by Pobjedonoszew, the procurator of the holy synod. Thanks to further donations the foundation stone could at last be laid on July 11, 1893. The plan of the church was designed in the Russo-Byzantine style of the eighteenth century by the architect Wiedermann, of Franzensbad. The forthcoming funds enabled the architect to set to work with such decision that on June 9 the building was ready for consecration. At this celebration the prior of the Kasan Church, St. Petersburg, assisted by archdeacons from Vienna, Budapest, Dresden, and Wiesbaden, performed the festal rites, whereupon the actual consecration was conducted by the Archdean Apraxin, the ecclesiastical head of the orthodox community of Karlsbad. The church was dedicated to St. Paul and St. Peter.

The building stands on a terrace which rises from the upper part of the Parkstrasse, a flight of steps leading up into the church from that street forming the main entrance. The roof is crowned with one central cupola of peculiar onion shape and a number of smaller ones of the same structure, grouped around it. One of these smaller cupolas forms the top of a pointed steeple in the back of the building. The walls are externally decorated by frescoes representing Christ crucified, and the two apostles to which the church is dedicated. The fine sculptures with which the interior of the church is adorned were fashioned by the artist Watzek, of Fischern.

The Czar showed his interest in the newly erected church by sending the secretary of the embassy at Vienna to represent him at the consecration services, and by decorating with medals the masters who directed the construction, a few of those who by donations and otherwise helped the enterprise being also similarly favored.

We are indebted for our reproduction of the building to Illustrirte Zeitung.

THE SUBSISTENCE QUESTION IN THE KLONDIKE REGION.

THE situation in the Klondike region is in some respects similar, as regards subsistence, to the situation that existed in the Selkirk Range, west of the Rockies, in the winter of 1884-85, prior to the construction of the Canadian Pacific Railway. The end of the track of the railroad (corresponding to the end of water transportation at Dyea) was on the west slope of the Rockies, in the Kicking Horse Valley. Some 50 miles beyond lay the Selkirk Range, which the railroad was to cross at an elevation of about 4,000 ft. above sea level. This range had the name of being one of the most difficult ranges in the Northwest to cross even in summer and on foot. It was covered with fallen timber of great size, trees of eight and ten feet diameter sometimes lying two or three deep. No feed grew there for pack animals,

except for a few weeks and in a very few places. The slopes of the valleys of the Beaver and Illecillewaet Rivers were marked with traces of hundreds of snowslides. The Indians of that region could never be induced to cross the range after October. The old guides, returning eastward from the range in October, insisted that the snowslides would destroy any parties sent in there in the winter. The average yearly snowfall on the upper part of the Selkirk Range is twenty-five feet, giving from eight to ten feet depth of settled snow on the level.

A pack trail had been completed across the range by the fall of 1884, and the wagon road had been advanced part way up the east slope of the range. In October orders came from Montreal to attempt at least some parts of the work on the range. These were the heavy work intended to be built at the Albert Cañon on the west slope; the completion of the wagon road across the range to a connection with the road from the west, and the forcing in of supplies over the route as far as possible. The writer was ordered to take charge of the advance work on the west slope, and to see that ample supplies were taken in, for which work abundant pack trains were provided.

In any such country the question of feed for the animals is the limiting factor. If the country produces this, supplies can be transported an indefinite distance. If no feed is found growing there, in a few days the animals will "eat the packs off their backs," delivering nothing beyond. Therefore, the advance of the wagon road is necessary, over which many times as much per animal can be transported. This was accomplished on the Selkirk Range, so that by the end of December ample supplies had been placed at winter quarters on the west slope. After that the wintering was accomplished in comfort—in tents for much of the winter and later in cabins. With abundant supplies, temperatures of −40° F. were not severely felt; and doubtless the low temperatures which appear to be so threatening in the Klondike region will be endured in similar comfort by those who have supplies. A duck tent of single thickness could be made warm enough by a sheet iron box stove of ordinary size. In the Klondike, as elsewhere, it will probably be a problem of food rather than of temperatures. The papers made the same terrifying predictions about the Selkirk cold that are now being made about the Klondike cold. In the Portland Oregonian, which I received via Winnipeg while on the Selkirks, the statement was made that human life could not stand the intense cold of a winter in such a region. I read that paragraph in the dead of winter in my cabin on the Selkirks, in an upper room without a fire, and with my coat thrown off because of the excessive heat from the rooms below. There is no cold which cannot be comfortably met by the man who has ample supplies of food and moderate supplies of fuel and clothing, even if his shelter be very inferior. With such supplies, the cold weather in most cases will be found a tonic to the system. It is not a question of the cold or of the snows, but of transportation.

The construction of the Selkirk wagon road was continued westward during the winter, and the road was connected with the road from the west in December. Temperatures of −35° F. were experienced during this construction, but did not stop the work. Such a wagon road is made largely by clearing and grubbing, with moderate amounts of earthwork, and some rockwork at peculiarly difficult points. The small proportion of earthwork permits the work to go forward, the work other than earthwork being readily done in cold weather. For a road to be used chiefly for sledding, and where heavy snows are expected, the grubbing may be very much reduced.

The winter time, which is being pointed to as the obstacle to advancement into the Klondike region, is really just the time to make such an advance by the overland route, if that advance be properly organized and pushed. In transportation, as in logging, winter is the time for work. Sleds will carry much greater loads over the snow than wagons will take later on rough roads. The snow slides caused only temporary interruption on the Selkirk Range. The slides that went far below the wagon road (or "tote road," as it is termed) left in general only moderate amounts of snow on the road. The slides which came to rest near the road, leaving a great depth of snow on the road, did not permanently interrupt travel. The snow was soon packed hard enough for teaming to be done over it as usual. It is stated that east of the Chilkat Pass, the winter snowfall is only about three feet; the topography of the country is not such as to create many large slides.

On the Rockies and Selkirks there were a few gradients, adverse to the haul of twenty feet per hundred, the difficulties being massed where helpers could be used readily. The Chilkat Pass, altitude 3,500 feet, shows eleven miles on one slope and ten miles on the other, or more than sufficient sustaining ground to give reasonable gradients for a wagon road, without deviation of route.

In attempting a comparison of the Klondike overland route with the Selkirk transportation, we are at a disadvantage, owing to the variations in miners' estimates of distances. Approximately the route appears to be as follows:

Dyea to head of navigation	6	miles
Southwest slope of Chilkat Pass	11	"
Northeast " " " "	10	"
On Lake Linderman	8	"
Portage	1	"
On Lake Burnett	26	"
Portage and Caribou River	3	"
On Lake Tagish	17	"
Portage to Marsh Lake	3	"
On Marsh Lake	24	"
On White Horse River to the rapids	27	"
" " " " below the rapids	30	"
On Lake Le Barge	31	"
On Lewis River	62	"
By land to Fort Selkirk (at the junction of the Lewis and Pelly Rivers, forming the Yukon River)	200	"
Total to the Yukon	459	"

Thence down the Yukon and up its tributaries by boat from 100 to 150 miles, according to the location of the mine or claim. As ten or a dozen claims would take up a mile of river under the old regulations, and as there are several thousand men already holding claims, a statement as to how far a man may have to go to reach his journey's end is necessarily an elastic affair by 50 or 100 miles. The last 25 or 50 miles would probably be on land. (The 200 miles of land travel to Fort Selkirk is given by some miners; others appear to travel this distance by boat.)

The Klondike overland route thus includes three important stretches of land travel, namely, at the Chilkat Pass, at the portion before Fort Selkirk is reached, and at the terminus of the journey. The first two stretches are traveled by all, and are a matter for public improvement; the last stretch will probably be a matter for packhorse work by the individual miner. The public route, with the exception of the first two stretches of land travel, is one affording a natural road in winter of the best sort of sledding, on frozen lakes and rivers, with a few short places requiring improvement. The blockade of which we hear most is that of the Chilkat Pass, where great numbers of men en route appear to be lying idle, awaiting the few Indian packers who are available, and who are charging from fifteen to twenty-five cents per pound for packing the twenty-seven miles to Lake Linderman. Thence the route is by boats, poor affairs made on the ground out of green whip-sawed lumber. This mode of transportation was attempted on the Columbia River, east of the Selkirks, where the rapids were much less formidable than the Northwestern Rapids are reported to be; but even the deep mud of the wagon road in spring was preferred by all but half a dozen parties. Anyone who has felt the power of water in the rapids of a mountain stream is apt to have too much respect for it to select such a transportation route if any other can be found.

We hear but little of the blockade at the stretch of land travel before Fort Selkirk is reached. It may be more serious than the Chilkat blockade, being further from feed or horses and from the large body of packers, or this stretch may be covered by boat by most of the parties. Some of the writer's acquaintances in the West are arranging to use both horses and dogs, the former at the Chilkat Pass, the latter in the later journey; the horses being killed for dog meat after the Chilkat transportation is completed. But dogs cannot be procured in sufficient numbers to meet the great demands of the situation. The probability is that the great mass of supplies will be transported to the Klondike region by winter transportation. Can this be done?

The difficulty of doing this by pack animals can be readily shown. Allowing only 20 pounds of feed per day per pony, and a load of 240 pounds per animal, in 12 days the pony has "eaten his load off his back," and must then be left to die, with no surplus delivered and nothing accomplished. This is just what happened in cases on the Selkirk Range, before the wagon road had been advanced; dead ponies were numerous along the trail. To place even 100 pounds per animal at the mines, a pack train must make the journey in less than seven days. The journey, even with the aid of water transportation, now takes over three times that length of time. In winter it has been known to take over 60 days.

On the other hand, assuming that a sled and team can take 3,000 pounds over a good sled road to the mines in about 20 days, we have about 800 pounds of the load consumed by the team and 2,200 pounds delivered. This is about a year's supply for a miner.

The weak point in the present situation appears to be the disorganized, individual character of the efforts to enter the country. At Dyea over 3,000 men are now said to be lying idle, awaiting packers. A tenth part of this number could construct a sled road across the Chilkat Pass in a few weeks, even if much rock work had to be done. No more provisions would be consumed by them than while lying idle. The Indian packers are too few to oppose effective resistance to such a construction; and the Pacific Coast Indian is not of the right make-up for a fight. There is a report that a company is being formed at Juneau to improve the transportation arrangements. A few weeks of work west of Fort Selkirk would probably secure a sled road at that stretch of land travel. For the rest of the distance, the winter will make the sled road. The eagerness to get to the mines this summer will probably prevent a proper combined effort until fall shows the blockaded parties the need of organized effort. Those who force their way in after August will reach the mining region poorly provided with supplies, worn out by their efforts to get in, and too late to prospect before snow. Those who go more deliberately and intelligently, after aiding in the construction of a sled road, will arrive in comparative comfort, better provided with supplies, with ample time in the winter to make a good general selection of country in which to seek a claim; and they will be on the ground before the arrivals by boat on the Yukon. If there be only three feet of annual snowfall in the Yukon country, as reported, there may be more wind than is generally experienced in regions of heavy snow, the latter being generally windless in winter. Continuous sledding, which the large travel will secure, will overcome this difficulty and keep the road open. The possibility of delivering supplies by vessels in the Yukon region part of the year is an obstacle to the construction of a good overland sled road, as is also the prospect of a railway route, both of these routes making the sled road a temporary affair.

The cost of a wagon road in mountain country, similar to the Selkirk Range, with wages, not including board, $1.75 per day, may be taken at $1,800 per mile maximum, with a rate as low as $100 per mile on fairly level easy stretches, and at locations about 150 miles from the base of supplies. If there be only 3,000 tons to be transported, and if only twenty cents per pound be saved by the construction of 250 miles of sled road, the economy of its construction can readily be calculated. For men en route with their supplies, a rate of $1.75 per day would be a good figure, as they would probably work for the cost of their subsistence, in order to save their own stores of food.

Sleds are readily made in the woods by an expert woodsman with ax and auger. I have had one made in a half day that would carry a ton. To handle 4,000 tons, including feed, several thousand horses would have to be shipped to Dyea, if the horses were to be sold at the mines, making no additional trips. With probably five round trips possible, a much smaller number would answer, depots of supplies of feed being established for the return trips.

Those who rely upon making an early entrance by the land route into the Klondike region after the streams are open for boating will probably make a mistake. The break-up in these upper tributaries of the Yukon will occur much later than in the lower Yukon, and vessels will probably reach Dawson City before the upper streams on the overland route have subsided from the freshets and have become navigable safely. In the late spring the ice will become rotten and an interval of cessation of transportation occur. The road will be neither sled road nor wagon road for a time under the melting snow and the spring rains. The late spring for the overland route must be the worst possible time, judging from experience elsewhere. The winter may be found the best possible time under proper organization and with proper effort.—Archibald A. Schenck, in the Railroad Gazette.

[Continued from SUPPLEMENT, No. 1130, page 18067.]

EDWARD DRINKER COPE, NATURALIST.*

THE studies of Cope on those classes which had earliest attracted his attention were more nearly completed than for any others. Many years ago he had contemplated the publication of monographs of the amphibians and reptiles of North America and happily he had at last finished his work.

In 1889 his monograph of the "Batrachia of North America" was given to the world as a Bulletin of the United States National Museum (No. 34). It forms a goodly volume of 525 pages illustrated by 84 plates† and 120 figures inserted in the text. No large country has a more elaborate and scientific exposition of the class than is given in this volume. A synopsis is furnished of all the families and genera wherever found, and detailed descriptions are supplied for all the groups and species represented in the zoological realm of North America; 31 genera and 107 species are recognized, and of these Cope had first made known about a quarter, 7 of the genera and 27 of the species having been described by himself. Shortly before his death, and during his last visit to Washington, he delivered to the National Museum the report on all the reptiles of North America which he had been long preparing. This was prepared on the model of his "Batrachia of North America," but will, of course, be a much larger work, inasmuch as there are nearly three times as many reptiles as Batrachians.‡ His last elaborate memoirs dealt with special anatomical features of the serpents and lizards, which he examined with the view of perfecting the system of those groups.

IV.

In 1864 he became especially interested in the fresh water fishes of the United States, and then, as well as in succeeding years, published enumerations and descriptions of many species. His first papers in 1864 and 1865 were "On a Blind Silurid from Pennsylvania" and a "Partial Catalogue of the Cold Blooded Vertebrata of Michigan;" in 1868 he published "On the Distribution of Fresh Water Fishes in the Allegheny Region of Southwestern Virginia," and in 1869 appeared a "Synopsis of the Cyprinidæ of Pennsylvania." In addition to these, various minor papers were published, and in some of them marine forms were considered.

When in Europe Cope had purchased a large collection of skeletons of fishes from all parts of the world prepared by Prof. Joseph Hyrtl, of Vienna, one of the most skillful practical anatomists of the day. He had a number of other skeletons made to represent missing types. With these as a basis he proceeded to recast the classification of fishes. The first contribution to the subject was embodied in an introductory chapter of his "Contribution to the Ichthyology of the Lesser Antilles," published early in 1871.

The same chapter, with the same title, "Observations on the Systematic Relations of Fishes," but with some modifications and additions, was later published in the Proceedings of the American Association for the Advancement of Science for 1871. This was a notable paper and replete with original observations of value. It was not, however, up to the standard of his work on amphibians and reptiles. The subject, indeed, was too vast and only a superficial examination was made of special parts. It was not a classification based on the examination of the entire structure, but rather an exposition of the development of a few particular characters, which more experience subsequently convinced him were of less value than he had supposed. Nevertheless, in some respects the proposed classification was much in advance of those previously adopted, and useful hints were given for the further improvement of the system.

Later Cope followed up this attempt at the reformation of the ichthyological system with several others especially treating of extinct types. One of them, "On the Classification of the Extinct Fishes of the Lower Types," was published in the Proceedings of the American Association for 1877. The results of his studies were summarized, in 1889, in "A Synopsis of the Families of Vertebrata," and two years afterward (1891) with modifications, in an article "On the Non-actinopterygian Teleostomi." These results were very valuable and attention was for the first time directed to the importance and morphological significance of the skeletal fin structures of the ancient fishes long confounded under the name of Ganoids. Instead of this single order (or sub-class) of the old systematists, he named four superorders of the Teleostomi or true fishes, and recognized seven orders, including the old Ganoids after eliminating the Lepidosteids and Amiids, which were referred to the Actinopterygians. Only two of the seven orders are represented by existing forms—one (Cladistia) by the bichirs of Africa and the other (Chondrostei) by the sturgeons.

His work on the extinct fishes was incomparably better than any that had been done before in the United States. He far surpassed all his predecessors, not only by his knowledge of morphological details manifest in the extinct as well as living forms, but by

* Presidential address by Prof. Theodore Gill before the annual meeting of the American Association for the Advancement of Science, August 9, 1897.

† The last plate is numbered 89, but five were canceled—80, 81, 82, 84 and 85.

‡ Cope's monograph of the reptiles will not include the tortoises, those having been left to Dr. G. Baur to monograph.

his keen philosophical instinct and taxonomic tact. But this philosophical instinct was sometimes at fault, and occasionally he indulged in the wildest speculations, for which he has, not unjustly, been taken to task. But even his blunders were the result of the facility of his mind in seizing and adapting the latest utterances of science.

One notorious case may be given. The great Russian embryologist, Kowalevsky, published a memoir sustaining the thesis that the Tunicates were members of the vertebrate phylum and that the larval stage of most of the species had the homological equivalent of the backbone of the true vertebrates. Cope foresaw the morphological consequences of this view and sought the vertebrates nearest the Tunicates. He settled upon some strange forms of the Silurian and Devonian times known as Pteraspids and Cephalaspids. They were the earliest known of vertebrates and therefore likely to be the most primitive in structure. Most of them had a shell-like encasement, composed of bone-like plates. He happened to find illustrations of the living Chelyosoma, a true Tunicate having a system of plate-like indurations of the integument, somewhat similar in appearance to those of some of the ancient fishes. It was assumed that this mere superficial similarity indicated genetic relationship. To those acquainted with the structure of Chelyosoma this approximation seemed strange indeed; its anatomy was known and the form is simply a well marked relation of the typical ascidians, but highly specialized by the development of integumentary plate-like horny indurations. Histologically and otherwise they were very different from the plates of the extinct armored vertebrates. Cope's guess was simply the result of the tendency to jump at conclusions which he was constantly obliged to curb, and unfortunately he rushed into print before he had time to think. He soon reconsidered the case with cooler mind, and abandoned his hypothesis. Few men were ever more willing to reconsider evidence and retrace false steps than he.

In spite of errors of detail and somewhat hasty generalization the ichthyological labors of Cope were unusually valuable contributions to science, and the progress of ichthyology has been much accelerated, not only by these labors, but by the investigations they challenged.

V.

Cope's attention was early drawn to the mammals. His first published article (1863) was a description of a supposed new shrew found in New Hampshire, and in 1865 he described various cetaceans. In 1868 he began the collection and investigation of the fossil mammals of the Western territory, and thenceforward devoted the larger share of his attention to the description and restoration of the numerous new species which he from time to time brought to light. The previous investigators of the extinct mammals of America had almost exclusively confined themselves to descriptions and illustrations of the crania and dentition, but a new era was introduced when Marsh and Cope sent out exploring expeditions or themselves collected. No parts of skeleton were neglected; all were collected. Gradually the numerous bones from different parts of the skeleton were identified, and finally many of the beasts of old were resurrected into skeletons almost as complete as those just divested of muscles.

The discoveries resulting from such thorough work quite modified or even overturned old conceptions. It became evident that there was a great contrast between the development of the mammals and that of invertebrates, and even, though in a less degree, of fishes. It appeared that there was a much more rapid process of evolution for the mammals than for the lower classes. All the mammals of the oldest of the Tertiary periods were strange and very unlike those of recent times, and no descendants of even the same families lived to be the contemporaries of civilized man. The views of the founder of vertebrate paleontology were also to a considerable extent subverted. Cuvier taught that there was always a co-ordination between the various systems of the animal frame and that from the remains or impress of one part the approximate structure of the other parts could be inferred. He even pushed this doctrine to such an extreme that he overlooked some obvious counter facts. One such case is so remarkable because it originated with Cuvier and was indorsed by Huxley* that it is worthy of mention here, and Huxley's introduction to it and translation of it may be given. Huxley himself protests against the too literal application of Cuvier's law and recalls Cuvier's own reserve:

"Cuvier, the more servile of whose imitators are fond of citing his mistaken doctrines as to the nature of the methods of paleontology against the conclusions of logic and of common sense, has put this so strongly that I cannot refrain from quoting his words.†

"But I doubt if any one would have divined, if untaught by observation, that all ruminants have the foot cleft, and that they alone have it. I doubt if any one would have divined that there are frontal horns only in this class; that those among them which have sharp canines for the most part lack horns.

"However, since these relations are constant, they must have some sufficient cause; but since we are ignorant of it, we must make good the defect of the theory by means of observation. It enables us to establish empirical laws, which become almost as certain as rational laws, when they rest on sufficiently repeated observations; so that now, whoso sees merely the print of a cleft foot may conclude that the animal which left this impression ruminated, and this conclusion is as certain as any other in physics or morals. This footprint alone, then, yields to him who observes it, the form of the teeth, the form of the jaws, the form of the vertebræ, the form of all the bones of the legs, of the thighs, of the shoulders, and of the pelvis of the animal which has passed by. It is a surer mark than all those of Zadig."

The first perusal of these remarks would occasion surprise to some and immediately induce a second, more careful reading to ascertain whether they had not been misunderstood. Some men, with much less knowledge than either Cuvier or Huxley, may at once recall living exceptions to the positive statements as to the co-ordination of the "foot cleft" with the other characters specified. One of the most common of domesticated animals—the hog—would come up before the "mind's eye," if not the actual eye at the moment, to refute any such correlation as was claimed. Nevertheless, notwithstanding the fierce controversial literature centered on Huxley, no allusion appears to have been made to the lapsus. Yet every one will admit that the hog has the "foot cleft" as much as any ruminant, but the "form of the teeth" and the form of some vertebræ are quite different from those of the ruminants, and of course the multiple stomach and adaptation for rumination do not exist in the hog. That any one mammalogist should make such a slip is not very surprising, but that a second equally learned should follow in his steps is a singular psychological curiosity.

I need scarcely add that the law of correlation applied by Cuvier to the structures of ruminants entirely fails in the case of many extinct mammals discovered since Cuvier's days. Zadig would have been completely nonplussed if he could have seen the imprint of an Agriochœrid, a Uintathœrid or a Menodontid.

I have given this quotation for two reasons: first, to indicate how the increase of our knowledge has revolutionized old conceptions; and second, to show how even the ablest of men may stumble.

Cope has been much criticised for the mistakes and false generalizations he made. Unquestionably he did make many. But error seems to be inseparable from investigation, and if he made more than the other great masters, he covered more ground and did more work. He was also, it must be admitted, more hasty than some others, in that he availed himself of the more frequent means of publication he enjoyed.

The great merit of Cope's work on mammals is that he always considered the old and new—the extinct and recent—forms together. He refused to be bound by consistency or by precedent, either set by himself or others. Fresh discoveries opened new vistas to him, and he modified his views from time to time and as often as he received new evidence.

He introduced many new families in the system and sought to improve the system by the comparison of all the elements of the skeleton. He came to the conclusion that the affinities of the ungulate quadrupeds was best expressed by the manner of articulation of the bones of the carpus and tarsus; he associated those having the "carpal and usually tarsal bones in linear series" in a great order which he called Taxeopoda, and contrasted them with the Proboscidea and typical Ungulata, which he named anew Diplarthra. In the Taxeopoda he gathered many extinct families and associated with them forms of the existing fauna known as the Hyracoidea, Daubentonioidea, Quadrumana and Anthropomorpha. I cannot altogther assent to this collocation, inasmuch as I think the common characteristics of the three groups last mentioned—especially the structure of the brain and the development of the posterior cornua of the ventricles as well as calcarine sulci—justify the old order Primates. Nevertheless an important character was first appreciated in the composition of the podial bones, and fresh insight was obtained into the relations of ancient types.

I can only name a few more of Cope's discoveries in this connection. One was the generalization of "trituberculy," or the original development of three tubercles to molar teeth, and that subsequent modifications of the corresponding teeth were based on this original plan. Another was the remarkable Phenacodus of the Eocene, which was considered to be nearly in the line of descent for the ungulates as well as the series culminating in man and which led him to the conception of the taxeopodous group.

The past history and genealogy of the camels and their relations were likewise elucidated. In the present epoch only two nearly related types exist separated by half the globe—the true camels of central and northern Asia and the llamas of the Peruvian Andes. Cope revealed numerous species from various Tertiary beds and showed that the type was originally richly developed in America.

VI.

Paleontology from more than one point of view may be divided into Invertebrate and Vertebrate. The subjects of the former are generally to be found in an approximately complete condition so far as the exterior is concerned, and early attracted the attention of investigators, often little familiar with recent zoology, and received names. The subjects of the latter—especially the higher types, as mammals, birds and reptiles—are rarely found, except in a fragmentary condition. Special knowledge of osteology, even to its minutest details, is requisite to successfully deal with such remains. Consequently the fossil vertebrates of the United States were neglected and left to the few who had cultivated the requisite knowledge to deal with them.

Another reason existed for the tardy attention to Vertebrate paleontology, which continued till nearly the last quarter of our present century in the United States. No deposits containing many fossil vertebrate remains had become known in the East. Zoologists interested in the past and in the genealogy of existing forms lamented the poverty of the United States, which contrasted with the richness of some parts of Europe. It was even thought that there was no hope of finding here such trophies of the past as the beds of the Paris Basin or those of Grecian Pikermi had yielded to European paleontologists. But all this was to be changed. Rumor had long before hinted that numerous skeletal remains could be found in certain parts of the wild West, but the information was very vague. Enough was known, however, to induce Prof. Marsh to visit certain deposits he had heard of. In 1870 he explored an Eocene lake basin in Wyoming, drained by the Green River, the main tributary of the Colorado, and therein found numerous bones belonging to almost all parts of the skeleton of some remarkable gigantic mammals which he called Dinocerata. The results of this exploration interested Cope in the highest degree. He visited the same region in 1872, and thenceforth his attention to the Vertebrate paleontology of the Western States and Territories was never interrupted. An intense rivalry arose between Prof. Marsh and himself which in time, it must be confessed, became very bitter. Nevertheless, as in most quarrels respecting facts, investigations were provoked by mutual recriminations which resulted in a more speedy accumulation of data and a more critical examination of these data than would have been likely under less perturbed conditions. Most of those data relate to morphological and anatomical considerations, and therefore belong rather to mammalogy and herpetology than to geology.

The relations of the ancient forms to each other in point of time; to those of other lands, and to those whose remains were embedded in other rocks had necessarily to be investigated. The earliest conclusions of Cope were brought together and published in 1879 in a memoir on "The Relations of the Horizons of Extinct Vertebrata of Europe and North America."* He attempted therein to synchronize, or, rather, homotaxially correlate the various ancient fauna of North America and "West Europe" from the "Primordial" to the "Pliocene." Naturally the greater part of the memoir was devoted to the consideration of the Tertiary divisions; of these he admitted for the American form six primary divisions, and four of these were dichotomously subdivided for the time. Of the primary divisions three were referred to the Eocene, one (White River) to the Oligocene, one (Loup Fork) to the Miocene, and one to the Pliocene. The exposition thus made represents views not very different from those now held, although, of course, modifications in details have since been necessary.

The evolution of the various animal, and especially mammalian types, was also continually the subject of Cope's researches, and he attempted to trace the passage from those of the most ancient periods to those of later ones.

(To be continued.)

ADDRESS BY SIR JOHN EVANS,

K.C.B., D.C.L., LL.D., Sc.D., Treas. R.S., V.P.S.A., For. Sec. G. S.; Correspondant de l'Institut de France, etc.; President of the British Association for the Advancement of Science.†

ONCE more has the Dominion of Canada invited the British Association for the Advancement of Science to hold one of the annual meetings of its members within the Canadian territory; and for a second time has the association had the honor and pleasure of accepting the proffered hospitality.

In doing so, the association has felt that if by any possibility the scientific welfare of a locality is promoted by its being the scene of such a meeting, the claims should be fully recognized of those who, though not dwelling in the British Isles, are still inhabitants of that Greater Britain whose prosperity is so intimately connected with the fortunes of the mother country.

Here, especially, as loyal subjects of one beloved sovereign, the sixtieth year of whose beneficent reign has just been celebrated with equal rejoicing in all parts of her empire; as speaking the same tongue, and as in most instances connected by the ties of one common parentage, we are bound together in all that can promote our common interests.

There is, in all probability, nothing that will tend more to advance those interests than the diffusion of science in all parts of the British Empire, and it is toward this end that the aspirations of the British Association are ever directed, even if in many instances the aim may not be attained.

We are, as already mentioned, indebted to Canada for previous hospitality, but we must also remember that, since the time when we last assembled on this side of the Atlantic, the Dominion has provided the association with a president, Sir William Dawson, whose name is alike well known in Britain and America, and whose reputation is indeed world wide. We rejoice that we have still among us the pioneer of American geology, who among other discoveries first made us acquainted with the "Air Breathers of the Coal," the terrestrial or more properly arboreal saurians of the New Brunswick and Nova Scotia coal measures.

On our last visit to Canada, in 1884, our place of assembly was Montreal, a city which is justly proud of her McGill University; to-day we meet within the buildings of another of the universities of this vast Dominion—and in a city, the absolute fitness of which for such a purpose must have been foreseen by the native Indian tribes when they gave to a small aggregation of huts upon this spot the name of Toronto—"the place of meetings."

Our gathering this year presents a feature of entire novelty and extreme interest, inasmuch as the sister association of the United States of America—still mourning the loss of her illustrious president, Professor Cope—and some other learned societies, have made special arrangements to allow of their members coming here to join us. I need hardly say how welcome their presence is, nor how gladly we look forward to their taking part in our discussions, and aiding us by interchange of thought. To such a meeting the term "international" seems almost misapplied. It may rather be described as a family gathering, in which our relatives more or less distant in blood, but still intimately connected with us by language, literature and habits of thought, have spontaneously arranged to take part.

The domain of science is no doubt one in which the various nations of the civilized world meet upon equal terms and for which no other passport is required than some evidence of having striven toward the advancement of natural knowledge. Here, on the frontier between the two great English speaking nations of the world, who is there that does not inwardly feel that anything which conduces to an intimacy between the representatives of two countries, both of them actively engaged in the pursuit of science, may also, through such an intimacy, react on the affairs of daily life, and aid in preserving those cordial relations that have now for so many years existed between the great American republic and the British Islands, with which her early foundations are indissolubly connected? The present year has witnessed an interchange of courtesies which has excited the warmest feelings of approbation on both sides of the Atlantic. I mean the return to its proper custodians of one of the most interesting of the relics of the Pilgrim Fathers, the log of the Mayflower. May this return, trifling in itself, be of happy augury as testifying to the feelings of mutual regard

† Delivered at Toronto, August 18, 1897.

and esteem which animate the hearts both of the donors and of the recipients!

At our meeting in Montreal the president was an investigator who had already attained to a foremost place in the domains of physics and mathematics, Lord Rayleigh. In his address he dealt mainly with topics, such as light, heat, sound, and electricity, on which he is one of our principal authorities. His name and that of his fellow worker, Professor Ramsay, are now and will in all future ages be associated with the discovery of the new element, argon. Of the ingenious methods by which that discovery was made, and the existence of argon established, this is not the place to speak. One can only hope that the element will not always continue to justify its name by its inertness.

The claims of such a leader in physical science as Lord Rayleigh to occupy the presidential chair are self-evident, but possibly those of his successor on this side of the Atlantic are not so immediately apparent. I cannot for a moment pretend to place myself on the same purely scientific level as my distinguished friend and for many years colleague Lord Rayleigh, and my claims, such as they are, seem to me to rest on entirely different grounds.

Whatever little I may have indirectly been able to do in assisting to promote the advancement of science, my principal efforts have now for many years been directed toward attempting to forge those links in the history of the world, and especially of humanity, that connect the past with the present, and toward tracing that course of evolution which plays as important a part in the physical and moral development of man as it does in that of the animal and vegetable creation.

It appears to me, therefore, that my election to this important post may, in the main, be regarded as a recognition by this association of the value of archeology as a science.

Leaving all personal considerations out of question, I gladly hail this recognition, which is, indeed, in full accordance with the attitude already for many years adopted by the association toward anthropology, one of the most important branches of true archeology.

It is no doubt hard to define the exact limits which are to be assigned to archeology as a science and archeology as a branch of history and belles lettres. A distinction is frequently drawn between science on the one hand and knowledge or learning on the other; but translate the terms into Latin, and the distinction at once disappears. In illustration of this I need only cite Bacon's great work on the "Advancement of Learning," which was, with his own aid, translated into Latin under the title "De Augmentis Scientiarum."

It must, however, be acknowledged that a distinction does exist between archeology proper and what, for want of a better word, may be termed antiquarianism. It may be interesting to know the internal arrangements of a Dominican convent in the middle ages, to distinguish between the different mouldings characteristic of the principal styles of Gothic architecture; to determine whether an English coin bearing the name of Henry was struck under Henry II, Richard, John, or Henry III, or to decide whether some given edifice was erected in Roman, Saxon, or Norman times. But the power to do this, though involving no small degree of detailed knowledge and some acquaintance with scientific methods, can hardly entitle its possessors to be enrolled among the votaries of science.

A familiarity with all the details of Greek and Roman mythology and culture must be regarded as a literary rather than a scientific qualification; and yet when among the records of classical times we come upon traces of manners and customs which have survived for generations, and which seem to throw some rays of light upon the dim past, when history and writing were unknown, we are, I think, approaching the boundaries of scientific archeology.

Every reader of Virgil knows that the Greeks were not merely orators, but that with a pair of compasses they could describe the movements of the heavens and fix the rising of the stars; but when by modern astronomy we can determine the heliacal rising of some well-known star, with which the worship in some given ancient temple is known to have been connected, and can fix its position on the horizon at some particular spot, say three thousand years ago, and then find that the axis of the temple is directed exactly toward that spot, we have some trustworthy scientific evidence that the temple in question must have been erected at a date approximately 1,100 years B. C. If on or close to the same site we find that more than one temple was erected, each having a different orientation, these variations, following as they may fairly be presumed to do the changing position of the rising of the dominant star, will also afford a guide as to the chronological order of the different foundations. The researches of Mr. Penrose seem to show that in certain Greek temples, of which the date of foundation is known from history, the actual orientation corresponds with that theoretically deduced from astronomical data.

Sir J. Norman Lockyer has shown that what holds good for Greek temples applies to many of far earlier date in Egypt, though up to the present time hardly a sufficient number of accurate observations have been made to justify us in foreseeing all the instructive results that may be expected to arise from astronomy coming to the aid of archeology.

SIR JOHN EVANS.

The intimate connection of archeology with other sciences is in no case so evident as with respect to geology, for when considering subjects such as those I shall presently discuss, it is almost impossible to say where the one science ends and the other begins.

By the application of geological methods many archeological questions relating even to subjects on the borders of the historical period have been satisfactorily solved. A careful examination of the limits of the area over which its smaller coins are found has led to the position of many an ancient Greek city being accurately ascertained; while in England it has only been by treating the coins of the ancient Britons, belonging to a period before the Roman occupation, as if they were actual fossils, that the territories under the dominion of the various kings and princes who struck them have been approximately determined. In arranging the chronological sequence of these coins, the evolution of their types—a process almost as remarkable, and certainly as well defined, as any to be found in nature—has served as an efficient guide. I may venture to add that the results obtained from the study of the morphology of this series of coins were published ten years before the appearance of Darwin's great work on the "Origin of Species."

When we come to the consideration of the relics of the early iron and bronze ages, the aid of chemistry has of necessity to be invoked. By its means we are able to determine whether the iron of a tool or weapon is of meteoritic or volcanic origin, or has been reduced from iron ore, in which case considerable knowledge of metallurgy would be involved on the part of those who made it. With bronze antiquities the nature and extent of the alloys combined with the copper may throw light not only on their chronological position, but on the sources whence the copper, tin, and other metals of which they consist were originally derived. I am not aware of there being sufficient differences in the analyses of the native copper from different localities in the region in which we are assembled for Canadian archeologists to fix the sources from which the metal was obtained which was used in the manufacture of the ancient tools and weapons of copper that are occasionally discovered in this part of the globe.

Like chemistry, mineralogy and petrology may be called to the assistance of archeology in determining the nature and source of the rocks of which ancient stone implements are made; and, thanks to researches of the followers of those sciences, the old view that all such implements formed of jade and found in Europe must of necessity have been fashioned from material imported from Asia can no longer be maintained. In one respect the archeologist differs in opinion from the mineralogist—namely, as to the propriety of chipping off fragments from perfect and highly finished specimens for the purpose of submitting them to microscopic examination.

I have hitherto been speaking of the aid that other sciences can afford to archeology when dealing with questions that come almost, if not quite, within the fringe of history, and belong to times when the surface of our earth presented much the same configuration as regards the distribution of land and water, and hill and valley, as it does at present, and when, in all probability, the climate was much the same as it now is. When, however, we come to discuss that remote age in which we find the earliest traces that are at present known of man's appearance upon earth, the aid of geology and paleontology becomes absolutely imperative.

The changes in the surface configuration and in the extent of the land, especially in a country like Britain, as well as the modifications of the fauna and flora since those days, have been such that the archeologist pure and simple is incompetent to deal with them, and he must either himself undertake the study of these other sciences or call experts in them to his assistance. The evidence that man had already appeared upon the earth is afforded by stone implements wrought by his hands, and it falls strictly within the province of the archeologist to judge whether given specimens were so wrought or not; it rests with the geologist to determine their stratigraphical or chronological position, while the paleontologist can pronounce upon the age and character of the associated fauna and flora.

If left to himself, the archeologist seems too prone to build up theories founded upon form alone, irrespective of geological conditions. The geologist, unaccustomed to archeological details, may readily fail to see the difference between the results of the operations of nature and those of art, and may be liable to trace the effects of man's handiwork in the chipping, bruising, and wearing which in all ages result from natural forces; but the united labors of the two, checked by those of the paleontologist, cannot do otherwise than lead toward sound conclusions.

It will perhaps be expected of me that I should on the present occasion bring under review the state of our present knowledge with regard to the antiquity of man; and probably no fitter place could be found for the discussion of such a topic than the adopted home of my venerated friend, the late Sir Daniel Wilson, who first introduced the word "prehistoric" into the English language.

Some among us may be able to call to mind the excitement, not only among men of science but among the general public, when, in 1859, the discoveries of M. Boucher de Perthes and Dr. Rigollot in the gravels of the valley of the Somme, at Abbeville and Amiens, were confirmed by the investigations of the late Sir Joseph Prestwich, myself, and others, and the co-existence of man with the extinct animals of the quaternary fauna, such as the mammoth and woolly haired rhinoceros, was first virtually established. It was at the same time pointed out that these relics belonged to a far earlier date than the ordinary stone weapons found upon the surface, which usually showed signs of grinding or polishing, and that in fact there were two stone ages in Britain. To these the terms neolithic and paleolithic were subsequently applied by Sir John Lubbock.

The excitement was not less when, at the meeting of this association at Aberdeen in the autumn of that year, Sir Charles Lyell, in the presence of the Prince Consort, called attention to the discoveries in the valley of the Somme, the site of which he had himself visited, and to the vast lapse of time indicated by the position of the implements in drift deposits a hundred feet above the existing river.

The conclusions forced upon those who examined the facts on the spot did not receive immediate acceptance by all who were interested in geology and archeology, and fierce were the controversies on the subject that were carried on both in the newspapers and before various learned societies.

It is at the same time instructive and amusing to look back on the discussions of those days. While one class of objectors accounted for the configuration of the flint implements from the gravels by some unknown chemical agency, by the violent and continued gyratory action of water, by fracture resulting from pressure, by rapid cooling when hot or by rapid heating when cold, or even regarded them as aberrant forms of fossil fishes, there were others who, when compelled to acknowledge that the implements were the work of men's hands, attempted to impugn and set aside the evidence as to the circumstances under which they had been discovered. In doing this they adopted the view that the worked flints had either been introduced into the containing beds at a comparatively recent date, or if they actually formed constituent parts of the gravel, then that this was a mere modern alluvium resulting from floods at no very remote period.

In the course of a few years the main stream of scientific thought left this controversy behind, though a tendency to cut down the lapse of time necessary for all the changes that have taken place in the configuration of the surface of the earth and in the character of its occupants since the time of the paleolithic gravels still survives in the inmost recesses of the hearts of not a few observers.

(To be continued.)

PRESERVATION OF FRESH GRAPES AND SEED POTATOES IN ITALY.

CONSUL-GENERAL JONES writes from Rome, June 24, 1897:

A recent bulletin of the School of Agriculture of Scandicci, Italy, describes experiments made by Prof. Marchi for the keeping of grapes fresh during the winter. A certain quantity of grapes comprising different qualities was hung up in a cool and dry place, all damaged berries having been previously removed; a second lot was packed in dry, pulverized peat in wooden boxes. At the end of four months the grapes that had been hung up had become decayed and had dropped off; on the other hand, those that had been packed in the boxes were found to be in fine condition. This is, therefore, a simple and economical method. Another one consists in gathering the bunches with a good bit of stem attached and immersing their tips in bottles containing water and pulverized charcoal. Experiments were also made for preserving seed potatoes by using corn shucks, sawdust, peat, and very dry sand. The three first mentioned substances gave the best results, while the sand proved a failure.

ALPINIA NUTANS.

OUR illustration shows a plant of a genus not common in English gardens, but frequently met with on the Continent. The Alpinias (Globba) form a rather large genus of stove, herbaceous perennials of much beauty of flower and elegance of habit. The flowers are dis-

ALPINIA NUTANS.

Color of flowers, pink. Height to which a plant will grow, 12 feet.

posed in terminal spikes, those of A. nutans being pink colored, of agreeable fragrance, and the spike drooping. The leaves are lanceolate, smooth, entire, and sheathed at the base. The roots are fleshy, like most Zingiberaceæ, and have much the taste and aroma of ginger. Alpinias require a high temperature, rich soil, and plenty of root space. Therefore, they succeed better when planted in borders or large tubs, and frequent applications of liquid manure and rich mulches are essential to vigorous growth, and without this, flowering is poor or altogether repressed. Soon after flowering the leaves assume a yellow tinge, and water should be withheld, but much drying off must not be practiced. They must not be exposed to less heat when at rest than at other times. The flowers appear in May. We are indebted to the kindness of the Marquise Strozza, Florence, who sent us a photograph, for the opportunity of furnishing our readers with a figure of Alpinia nutans.—Gardeners' Chronicle.

The attention of the German and French governments has recently been directed, says the National Druggist, to a brand of cigarettes that has become a fashionable favorite under the name "Bouts dorés," or "Gilt ends." The end intended to go between the lips is covered with a metallic leaf which is claimed to be gold, but which analysis shows to be an imitation of gold attached to the paper by lead chromate. In another form, called "Bouts Argentés" (silvered ends), a false silver leaf is attached to the paper by white lead.

THE SCIENCE OF HUMANITY.

By W. J. McGEE.*

OF THE SCIENCE OF ANIMAL MAN.

THE domain of anthropology is vast, and, partly by reason of its very magnitude, is sometimes deemed indefinite; yet, in the light of the history of science in general, its limits and subdivisions may easily be outlined.

History and analogy combine to show that the study of man began with wounds and diseases and grew into surgery and medicine, which were at first thaumaturgic, but gradually became rational or scientific; and in this way definite knowledge of the human body gradually accumulated and anatomy and physiology, with various ancillary sciences and subsciences, took form and function. Meantime the organs of the human body were compared and identified with those of beasts and birds (which were long the better known), and comparative anatomy was established; but it was not until observation and generalization were fertilized by scientific zoology that the study of structures in their functional aspect took shape in morphology. Under the influence of humanitarian therapy and the unprecedented stimulus of the Darwinian doctrine of development, the investigations of the last century, and particularly the last quarter century, have extended from structures to functions, and these, through the fruitful science of embryology, to human ontogeny and phylogeny—to the individual and generic evolution of man considered as an animate organism. Accordingly, there are several branches of science which deal alike with the human organism and the various other animal and even vegetal organisms of the great vital series in which man is usually, though not invariably, considered the culminating and crowning form. Here anthropology and biology blend; but it is convenient and desirable to distinguish that division of the science of man which deals with the organic features of the order Bimana, and this science or subscience is frequently called somatology. Although the oldest and the simplest among the divisions of the anthropologic sciences, somatology comprises various special branches of knowledge commonly classed as sciences, including pathology, physiology, etiology, etc., representing the specific methods and purposes of particular classes of investigators.

The early books and maps of civilized nations show that explorers and pioneers were profoundly impressed by the faraway peoples encountered in their wanderings. There are not only accounts but pictures of headless men with faces in their chests, of Cyclops with single eyes set skyward, and of other impossible monstrosities in human semblance; even since zoology became fairly definite, accounts of ten-foot giants in Patagonia and three-foot pygmies in central Africa and other lands remote or hidden have gained currency and credence. As exploration continued, the unconscionable extravagances of vision were gradually corrected, and the explorers came to see alien races in proper form and something like proper stature; yet the interest in the stranger peoples remained unabated and led to systematic observation and record. Borrowing methods from biology, the observers or their interpreters sought to classify the men of different continents and provinces and islands by somatic characters—by stature, color of skin, color and texture of hair, color and attitude of eyes, form of feature, form and size of skull, peculiarities of long bones, etc.; and, as the researches became definite and fruitful, they were combined in a science of races called ethnology. This science has much in common with biology and is a direct outgrowth from the group of sciences pertaining to the human body combined under the term somatology.

After centuries of unscientific and unsuccessful search for the seat of the soul through baseless deduction and blind introspection, certain thinkers began to profit by contemporary researches in anatomy and physiology; and as eye and mind were trained—even as the eye and mind of the traveler were trained not to make monstrosities out of unfamiliar races—the form and function of the nervous system were gradually recognized, and the dominance of the brain was finally established. Only within a generation or two has the brain been investigated in a scientific way and with due appreciation of the importance of that marvelous ganglion preformed in the articulates, enriched throughout the long line of vertebrates, and perfected in the ultimate mammalian form of the genus Homo; yet during the present quarter century the research has been organized in a science already cultivated in many lands and taught in most of the leading universities. The earlier promoters of this science approached the subject haltingly from the speculative or deductive side, and perhaps for this reason the science is named not so much from the organ itself as from its product, psychology. This modern science is not to be confounded with the fantastic notions sometimes foisted under the same designation which do little more than obstruct progress; the parent stock of the science was indeed speculative—as is most knowledge in the beginning—but so soon as the graft of somatology was affixed it became fruitful. It is to be noted that while somatology is essentially biotic, and ethnology is biotic in so far as it rests on bodily features, psychology pushes beyond the domain of biology proper, partly in that the human brain owes its perfection of development to the essentially human attributes, partly in that the science, as commonly defined, embraces both brain and mind, both organ and product.

So there are three well-established and widely recognized sciences whose object-matter is man considered as an organism; by some students—especially those of past decades—they are held to constitute the whole of anthropology; by others they are combined as physical anthropology and regarded as including only the animal side of man, but excluding nearly the whole of the essentially human side—nearly, but not quite the whole, since the field of psychology is common ground. This is the view of several modern anthropologists, and is that held in this writing.

OF THE POTENCY OF DEVICES.

Passing from that portion of the domain of anthropology which deals with man as an animate genus, there is found another and still broader portion occupied by that which man does as a sentient, volitient and intelligent being. It is true that this portion of the domain is less definite than the other, yet, in the light of intellectual progress, its limits and subdivisions also may be outlined, albeit in some measure provisionally.

The early explorers who came home laden with travelers' tales sometimes brought also more tangible cargo in the form of strange wares; and so the handiwork of the world gradually came under the observation of students, and in time museums were built partly to accommodate the constantly increasing collections of primitive and alien arts. Meantime observant persons in many lands were attracted by relics of archaic culture in the form of implements, weapons, ornaments, apparel and habitations, as well as burial places sometimes containing the bones of the ancient artisans; and these, too, were collected and museums were built to accommodate them in connection with the artificial material gathered among the living peoples of distant lands. As collectors and collections multiplied, the work was organized; and, although the initial stimulus came from observation in remote countries, the interest grew inward—as is the way of advancing knowledge—and the local research for the rare relics of past ages was the first to receive name and character as the science of archæology. As observations multiplied, resemblances were found between the culture products of remote times and remote places. The arts of primitive peoples were found to vary in a manner corresponding more or less closely to race, and thereby ethnic research gained new impetus and served in turn to guide research in the prehistoric; so archæology and ethnology became mutually helpful and grew apace and came to be intimately associated in most minds, despite the fact that the one is concerned primarily with what man is, the other with what man does; and in some circles these branches of inquiry came to be regarded as constituting the whole of anthropology.

At first the products of ancient and alien handiwork were accepted at their token value, much like the chemic elements before Avogadro, the planetary movements before Newton, our sun and others before the doctrine of the persistence of motion, the organic species before Darwin; but within a generation or two it has come to be realized that they possess an innate value as exponents of intellectual activity—as medals of human creation collectively attesting the birth and growth of discovery and invention, design and motive, and all other human faculties. Perhaps the time has not come for defining this stage in the progress of anthropology; it may be that the transition is not yet complete, or that the relations are too complex for easy grasp; yet it seems clear that when the anthropologist first saw in the implement of shell or stone an index to the mental operations of the implement maker hardly less definite than the written page to the thought of the writer, the science of man rose to a higher plane with a bound comparable to those marking great epochs in the development of the other sciences.

* Vice-presidential address before Section H of the American Association for the Advancement of Science, delivered at Detroit, August 9, 1897.

Now in science each advance gives a new standpoint from which a broader view may be gained; and with the recognition of what may be called the dynamic aspect of artificial objects, the way was prepared for further progress. It was soon perceived that the simplest devices are supplements to or substitutes for bodily organs—that the knife of shell or tooth or stone is a supplement to teeth and nails, that the hammer stone multiplies the efficiency of blows, and that the missile is equivalent to an indefinite prolongation of reach; and accordingly it was realized that, in so far as he is a maker and user of implements and weapons, even the lowest savage rises above the plane of purely animal life. It was next perceived that even the simplest devices react on the organisms in various ways. The substitution of the shell knife for nails and teeth diminishes the exercise, and hence the vigor of these organs, and removes them from the category of characters subject to development through the survival of the fittest in the strife for existence, so that in so far as he employs devices in lieu of organs the savage passes beyond the realm of organic development by natural selection; at the same time the exercise of making and using artificial devices in lieu of natural organs tends to develop distinctively intellectual or cerebral characters; so that the effect of competition in the use of devices is not only to remove man from the realm of the biotic, but to set him on a definite course of development in a new realm—the realm of the artificial or essentially human. As the view of the artificial continued to broaden, it was perceived that while the simpler devices may appertain to individuals, they are not an integral part of the individual like the organs which they supplement, but may and do pass from hand to hand and from group to group; also that the use of a device by one person prompts others to acquire and use similar devices, which they are able to do through mere exercise of volition, so that each discovery or invention is at once the germ of a line of devices and a stimulus to intellectual power; and thus it was recognized that there is a strong communal tendency in the realm of the artificial, that the tendency of the development of devices is toward interchange and co-operation, yet ever of such sort as to augment intellectual power and elevate the human above the subhuman.

In the light of the dynamic interpretation of devices it is easy to perceive the trend of superorganic succession, or development of the artificial, and to contrast it with the course of biotic evolution; the substance or substratum of the latter is living matter, that of the former any matter, living or dead, with which man chooses to deal. The mode of this is slow elimination of the unfit and unpremeditated survival of the fit, the method of that is immediate imitation and designed improvement of the ingenious; the tendency of biotic evolution is toward organic differentiation, that of artificial development mainly toward organic persistence, with endless multiplication and integration of devices. The effect of the one is individual or egoistic, that of the other communal and altruistic. With the recognition of the dynamic and successional aspects of artificial devices, anthropology gained a new significance; for to its objects-matter in the form of the human body and human races and the human brain there was added the whole series of artificial devices and the exceeding potent intellectual activities which these devices represent, and this addition is the basis of what is here styled the Science of Humanity.*

OF THE ACTIVITIES OF MAN.

When artificial devices were interpreted in terms of activities, a new classification of human handiwork arose. At the same time the activities themselves became objects of research, which soon passed beyond the collections, and extended to the multifarious material devices in daily use among living peoples in the various stages of civilization from savagery to enlightenment; still later the research was extended to the intellectual or non-material devices which pre-eminently distinguish mankind, such as law, letters, and learning, in their numberless aspects. The study of the activities is now sufficiently advanced to indicate, at least provisionally, their relations among each other and to the merely organic processes; they may be arranged in the inverse order of their affinity with the vital.

1. The primary activities of mankind are connected with more or less spontaneous sensations of pleasurable character. They arise and expand in fairly definite order; among known primitive peoples they appeal chiefly to the senses, and among more advanced peoples they appeal largely to the emotions and the purely intellectual faculties; they root in sports, games, and decorations, and mature in the fine arts of painting, sculpture, the drama, poesy, and music, i. e., they constitute the esthetics. The artificial devices growing out of these activities go far toward filling those museums of the world devoted to archaic and ethnic material; and nearly a third part of current anthropologic literature is devoted to this class of objects and the activities which they represent. These activities and activital products form the object-matter of a broad and fruitful field of inquiry known of late as esthetology.

2. Intimately connected with the primary activities, and also originating in spontaneous vital processes, though becoming dominant only by organization through exercise and volition, there are other activities tending toward the maintenance of physical welfare. From a simple beginning in occupations akin to those of the beasts, they arise and expand with each step in cultural advancement from savagery to enlightenment; at first confined to food getting, they extend also to the making of apparel, the building of habitations, and eventually to the supply of intellectual demands, i. e., they constitute the industries of common parlance. The material devices growing out of the industrial activities have enriched anthropologic museums almost equally with those growing out of esthetic activities; and probably a fourth part of the current literature of anthropology is devoted to them and the activities by which they are produced. Together they form the object-matter of a broad and rich science commonly called technology.

It is to be noted that the greater part of the material investigated by the archeologist pertains also to the fields of esthetology and technology, though these are far broader in that they extend not only to a greater variety of activital products, but to the activities themselves. It may also be noted that both esthetics and industries, originating as they do in vital processes, are primarily individual, though they become collective partly through combination with higher activities; while the higher activities of the series are primarily collective. It is noteworthy, too, that the two lower classes of essentially human activities rest on a material basis and are represented primarily by material devices, while the activities of higher planes rise above the material in their essential character and are only incidentally represented by material devices.

3. The activities of the third class are connected with collective relations; and since they grow out of consanguinity or family relation they may be said to have a biotic germ. In general, the products of these activities originate as customs which grade into regulations and later into laws, and are perpetuated in tribal, national, and other institutions. The activities and their products are most intimately connected with and indeed form the chief basis of cultural progress. In the first culture stage, corresponding to what is commonly called savagery, the collective or social relation is based on kinship traced in the maternal line; in the stage commonly called barbarism, social relation rests on kinship traced through the paternal line—these stages forming tribal society. In the third stage the social organization passes from patriarchy through feudalism or an equivalent intermediate condition not yet formulated to that stage of individual property right in lands and goods which is commonly called civilization; and men are now passing into the stage characterized by intellectual property right which is commonly called enlightenment—the organization in the last two stages being essentially nonconsanguineal and constituting what is sometimes called national society. The several activities and activital products belonging to this class form the object-matter of a fecund science commonly called sociology—though the day of final agreement concerning the definition of the term is not yet.

4. In some measure the activities of the fourth class are an outgrowth of those of the third, since they are essentially superorganic and may be regarded as a means of establishing and maintaining relation; they comprise expression, pantomimic, oral, and graphic. Like the other activities, they arise and expand in a certain order; beginning with what is somewhat incongruously called gesture speech and with rudely articulate language, they mature in oratory and literature; and it is significant that the lines of development, so far as ascertained, run counter to those of biotic evolution, in that they are almost wholly convergent instead of divergent—so that these activities pertain, in every essential respect, to the superorganic realm of humanity. The principal activities are speech and writing; the tangible products are legend and literature—but the rich and ever growing content of these products is knowledge. The activities of expression and their products are commonly combined as the object-matter of another science frequently called philology—though in this case, too, there is diversity in definition and also in designation.

5. There remains a class of elusive and Protean yet immeasurably potent activities which come so near the Ego and are so hard to grasp and difficult to convey that it would seem almost hopeless to attempt to define them; they are the essentially intellectual activities which form the motive and burden of expression, and their products comprise beliefs, opinions, knowledge, wisdom, and all other purely intellectual possessions. These activities also arise in a definite order which is set forth summarily in earlier paragraphs; and by the most systematic thinkers they are considered to mature in science. The activities and their products are so obscure and so diverse that they have not been combined and named in the vernacular; yet they are by some students regarded as the object matter of one of the broadest of the special sciences, sophiology.*

So there are five classes of essentially human activities and activital products, each so rich in phenomena and principles and so far distinct from all other classes of things as to constitute an adequate basis for a science; they are the fine arts or esthetics, giving basis for esthetology; industries, forming the object-matter of technology; organizations or institutions, affording foundation for sociology; language and literature, with their science of philology; and the great plasma of knowledge, forming the ill-defined but all-important object-matter of sophiology. The five fields of research pertain primarily to man, and thus represent anthropology; yet even casual survey of their extent and character renders it evident that they pertain not at all to the animal side of man, but wholly to that side which intellectual man alone possesses—they are five sciences of humanity. Partly to distinguish them from the three distinct branches of knowledge concerning animal man, partly to fix their place in the body of knowledge, they have recently been combined under the term demonomy;† and this system of organized knowledge concerning wholly human things may fitly be designated the science of humanity.

As knowledge arises, it is applied to the promotion of happiness and welfare; this has been true of unorganized and unconsciously organized knowledge throughout the history of mankind, and is especially true of definitely organized knowledge, which thereby becomes applied science. Now knowledge concerning the human activities, even while unconscious or half conscious only, reacts upon and shapes the activities in such manner as constantly to increase their potency. Some of the ways in which the science of humanity stimulates and strengthens human activities are especially noteworthy.

1. While the great domain of anthropology is divisible into an animal side comprising three broad sciences and a human side made up of five still broader fields of research, other classifications are possible, and indeed of special utility when directed toward the practical application of the science to everyday affairs—for any assemblage of facts and relations may be classified in as many ways as there are purposes of classification. Experience shows that there is a peculiar advantage in classifying certain sciences by method of research rather than by the objects under investigation. Classified in this way, anthropology comprises (1) demography, i. e., the enumeration and description of men, activital products, etc.; (2) human geography (or anthropogeography), dealing with the geographic distribution of peoples and their products; (3) political economy, which is concerned primarily with applied social forces and their products; (4) history, which deals with the rise and fall of peoples and nations; and (5) philosophy, which scrutinizes materials and forces and sequences and seeks the causes of growth and decadence among human things. This classification traverses the same domain as the more general one, and serves to bring out the same facts and relations in somewhat different light, i. e., it is artificial rather than natural, technical rather than logical, subjective rather than objective, directive rather than creative; in brief, it expresses applied science rather than original research. For certain purposes it is desirable to combine the classifications and define special fields of inquiry by the coincidence between the two, as has recently been done happily by Giddings* and others; for the lines of thought represented in the two systems are strengthened by interaction—the one may be said to represent science and the other statecraft, and the two combine to advance mankind in knowledge and power.

2. At the outset the science of ethnology was closely affiliated with zoology, representing indeed little more than the concentration of biologic inquiry on a single order of animate organisms; but with the recognition of human activities, this science was raised to a new plane. The applications of demonomy in the classification of peoples and races are many and sweeping; already the natives of the western hemispheres are classified primarily by language and incidentally by other demotic features rather than by any or all biotic characters; already the great stages in human progress from savagery to enlightenment are seriated in terms of social organization in lieu of those of the bodily features with which the biologist is wont to deal; already the present day ethnologist gives first thought to the arts, industries, institutions, languages, and ideas of the races rather than to any or all of those individual features comprised in stature and form and color; already, indeed, the recognition of human activities and the course of human development has served to revolutionize the science of races no less completely than the older sciences were revolutionized by recognition of force and sequence; and just as the new chemistry, the new astronomy, and the new geology are distinguished, so it is meet to distinguish a new ethnology as a science of artificially organized groups rather than a science of mere upright animals.

3. With the rise of knowledge concerning activities, it was perceived that the primary function and eventual design of devices have always been to extend and increase human power, to enable man to control plants, subjugate animals, and to evade or utilize sun and storm, i. e., to make conquest of lower nature; accordingly it was recognized that, while the human characters reflect environment measurably, as the purely biotic characters do fully, it is the essential tendency and function of man to control, rather than to be controlled by, his environment. This human power did not spring into being full-fledged—indeed modern science knows no Minervan birth—but grew up slowly through the exercise and gradual strengthening of volition and the evolution of design; so primitive peoples are measurably controlled by their environment, while the control diminishes with successive culture stages up to that of enlightened man, who dominates by multifarious devices nearly every physical force. Examination of the successive stages in emancipation from environment brings to light many significant relations; thus it is found that when two or more primitive peoples of similar culture are subjected to similar conditions of environment their minds respond in similar ways, so that similar devices are discovered or invented; and recognition of this law of human progress has served to correct some of the most persistent misapprehensions by which anthropology, like all other sciences in their infancy, has been burdened. At the same time the recognition of progressively increasing conquest over the inorganic and the organic merely has served to define and dignify man's estate at the head of all nature.

4. Although certain human characters and characteristics were already under investigation, it can hardly be said that mankind in general came into the domain of scientific inquiry until the Darwinian doctrine of evolution was accepted; accordingly, anthropologists at first regarded man as subject to the law of organic development through the survival of the fittest. Then came the recognition of activital development in contradistinction from organic development; and the pendulum of opinion swung back so far that most modern anthropologists implicitly assumed the human generic form to be fixed and final, so far as organic development is concerned. It now appears that the pendulum swung too far; for a long series of highly significant yet but half appreciated observations indicate that, just as the human mind dominates the materials and forces of lower nature, so may it measurably control and fashion the organism in which it is embodied—already hygiene and gymnastics have improved unnumbered physiques and lengthened the days of thousands; already leading educational institutions maintain physical departments in which they undertake so to shape and strengthen the limbs and lungs and even the heart and bone of the matriculate that he may be graduated sound in body as strong in mind; yet these indications would seem only to point the way of progress and promise still better things in human development as later generations rise.

* The enlargement of the domain of anthropology as here set forth is regarded as marking the most important epoch in the development of this science, one of the most important in the history of science in general. Several investigators have contributed to it; perhaps the earliest, one of the most voluminous, and certainly the most original of these contributors is J. W. Powell, whose preliminary writings have appeared in a large number of addresses, official reports and minor papers, though his final results are not yet published.

Acid-proof Cement.—A coating which may be used to protect vessels from the action of the strongest acids is prepared by thoroughly mixing 2 p. of powdered asbestos, 1 p. of barium sulphate and 2 p. of soluble glass solution of 50° Be. gravity. For the feebler acids a glass solution of 30° Be. may be used.—Pharmaceutical Era.

ELECTRICAL NOTES.

The sea going car on the Brighton and Rottingdean Electric Railway has resumed work.

The installation of a system of electric car lines at Vienna is being considered, and it is hoped that the service will commence on May 1, 1898.—Electrotechnische Rundschau.

A blast was fired by lightning at Rockland, Me., on June 28, killing one man and badly injuring two. Eight loaded holes were being connected for firing, when lightning struck the battery wire, thus prematurely firing the charges.

A fifth telephone connection is to be laid between Stuttgart and Goeppingen, Germany, as the four used hitherto are becoming insufficient for the growing service. The line is also to be extended to Geislingen.—Electrotechnische Rundschau.

Recently Marconi's experiments in telegraphy without wires were renewed at the Ministry of Marine, at Rome, before a number of journalists. Signor Marconi was to exhibit his apparatus before the King and Queen of Italy, and afterward proceeded to Spezia to transmit messages between different ships intercepted by other vessels.

The latest novelty in the way of buoys is an electric lamp supported by a buoy of 100 lb. weight, sufficient to bear up three men. It is provided with a secondary battery which preserves its charge for two months, and can supply current for lighting the 16 candle power lamp for six hours. The light is projected through a lens, and is visible a mile off.—Revue Industrielle.

The new Berlin Omnibus Company, says the Elektrotechnische Zeitschrift, intends to run a trial accumulator vehicle, and the order for its manufacture has already been placed. It is to be of the same size as an ordinary omnibus, with seats on the roof, and the cells will be placed both under the inside and outside seats. The cells will be charged after every two journeys (the length of the journeys is not mentioned). The company anticipates a considerable saving by the use of electrically propelled cars, as 10 horses daily are now required for an omnibus.

An electrical exhibition was opened in Riva, in the Tyrol, on May 27 last. Its main object is to draw the attention of industrial and agricultural circles in southern Tyrol to the manifold applications of electric power. Very little use is made of the waste water power in this district, though it is very abundant. The small market towns of Pergine and Roncegno have electric light, and also the health resort Arco, and Riva started a large water-driven generating station last year, but that is all. The most interesting feature of the exhibition, says the Wiener Zeitung, is the collection of light electrically-driven machines and labor-saving appliances shown by the Technological Trade Museum. A large number of the machines exhibited are shown in action.—The Electrician.

At Capetown considerable trouble was lately caused by an electric tramway line which had been laid in proximity to the submarine cable of the Eastern and South African Telegraph Company. This cable is looped around Table Bay in order to be out of the way of any anchors, and is connected to the wire on land at Adderley Road. For some 2,000 yards the trams run at a distance of about 900 yards from the cable. It was noticed as soon as the tramway was run that whenever a car started, a kick was given by the receiver. When sand or any other obstruction came between the wheels and the rails, the lines traced by the telegraph were uneven. All attempts to get rid of these troubles proved vain until a secondary cable was laid alongside the original one, for ten miles, connected on the land end to the receiver and on the further end to earth.—L'Electricien.

Owing to the intensity of the electric light used on board of men-of-war, men are frequently affected with eye complaints, which in some cases have led to total blindness. It is said that eyes in which the iris is not heavily charged with pigments—that is to say, gray and blue eyes—are more likely to be injuriously affected than brown eyes. These eye troubles are ascribed to two causes—viz., the intensity of the light and the action of the ultra-violet rays. Oculists recommend the interposition between the eye and any powerful light of a transparent substance which will intercept the ultra-violet rays, such as, for instance, uranium glass, which is yellow. The French naval authorities supply dark blue glasses for the use of those men who have to do with search lights, etc., and the cases in which injury has been caused to the eyes were those of men who had neglected to use these spectacles, which, however, do not appear to afford any protection against the ultra-violet rays.—Revue du Cercle Militaire.

The question of a proper or desirable unit for rating the efficiency of an electric plant is still open, says Power. If the pounds of coal per kilowatt hour be taken, the question immediately arises, "What kind of coal?" This objection cannot be met by substituting the calorific value of the coal and making the unit of comparison thermal units in coal per kilowatt hour, for a thousand heat units in one kind of coal are more available than in another, so that the question, "What kind of coal?" still stands. The money cost per kilowatt hour is not a correct basis for comparison of efficiencies, except among stations which are similarly situated with regard to cost of fuel. Professor William S. Aldrich proposes the kilowatts per million thermal units in the steam supplied to the whole station on a basis similar to that in vogue for pumping plants. This is an admirable system for specifying the efficiency of a pumping engine, and would be equally good for a steam dynamo, but, aside from the difficulty of determining accurately the heat units supplied to a station which will always define the heat unit as a scientific rather than a popular method, there is the fact that such a rating leaves out of account altogether one of the principal features of the station—the steam generating plant. Probably the most satisfactory popular expression of the efficiency of a station is the pound of coal per kilowatt hour, with a statement as to the class of coal used. In reporting a test, of course, all the data should be given, so that the reader may select that unit in which he is accustomed to think, and so that the reason for the result may be apparent.

MISCELLANEOUS NOTES.

The use of paper for floorings has many advantages over that of wood. Paper, being a bad conductor of sound and heat, insures on the one hand privacy, and on the other a comfortable temperature in both summer and winter. To the foot a paper floor, though harder and more durable than wood, gives a similar impression to that produced by linoleum, and, being made in one piece, has no cracks to shelter all kinds of vermin.—Monatschrift für den Baudienst.

Rubber mats are now made for use in the bottom of porcelain bath tubs, the glassy surface of which is liable to cause painful accidents from slipping. The India Rubber World says that many a case of broken rib or serious bruise has been caused by a bather falling against the iron rim or sides of highly finished tubs. Cork mats have also been used, but are less desirable than rubber, as they chip off from frequent soaking, and pieces are apt to clog the pipes.

Very good porous bricks are made by the director of a mine in Libuschin, near Kladno, Bohemia, from a mixture of clay and bituminous slate. This latter is obtained in great quantities in the process of washing coal. The bricks made from this material are cheap, very strong and only about one-half as heavy as the ordinary stones. They are, moreover, bad conductors of sound and heat. At Vienna the price paid for them is $6.25 per thousand.—Monatschrift für den Oeffentlichen Baudienst.

Dr. Schott, of the Jena laboratory, has made a discovery by which he is enabled to raise the luminosity of the incandescent gas light by some 60 per cent. He noticed a considerable increase in the light given by a burner if the air struck the mantle at right angles instead of, as usual, almost parallel. He has devised a burner in which the air is fed into the flame so as to stream from the center against the mantle, the glass chimney being widened and the usual circular opening at the bottom closed.—Prometheus.

A new use of aluminum has been discovered in the manufacture of reproducers for talking machines. The reproducer is the apparatus which holds the vibrating diaphragm of glass. Heretofore the recorders and reproducers of talking machines have been made, as a rule, of hard rubber. For hard rubber, aluminum has been substituted, with what is regarded as much success. It is claimed that the blasting, blaring, or "chattering" as it is called in the trade, which is often noticeable in the performance of the talking machine, is almost completely absent when an aluminum reproducer is used.

A patent has recently been taken by the Society of Chemical Works at Mannheim, Germany, for a new process for the preparation of potassium or sodium thio-sulphate. The chloride of the metal is first treated in the usual way, a bicarbonate being obtained, then this product is acted on with sulphur dioxide in the presence of sulphur, water and sal ammoniac; the escaping carbon dioxide and the ammonia, taken up from the ammonium chloride, once more serve to prepare the carbonate from the chloride, so that the same material is used over and over again. The process is carried out in a series of retorts, some of which serve for the production of the bicarbonate, while in the others this is transformed into thio-sulphate.—Die Chemische Industrie.

Messrs. Siemens & Halske, of Berlin, have invented a process for purifying starch, which is based on the oxidation of the cellulose into oxycellulose by oxidizing agents and nascent chlorine, the latter being prepared by the action of hydrochloric acid on potassium permanganate. The starch is dissolved in cold water, then the manganate is brought to act on it, and this process is continued until the salt is no longer discolored. After this the starch must be bleached, for the manganese peroxide produced in the reaction has given the substance a brown color. This bleaching is readily effected by the addition of sulphurous acid, which removes the peroxide. The oxidation of the cellulose is effected by shaking the brown starch in a bath of dilute hydrochloric acid. When the product is totally soluble in an alkaline solution, it is ready for bleaching.—Revue Scientifique.

The Department of State publishes the following from Consul Monaghan, dated Chemnitz, May 17, 1897: Berlin and Leipsic are boasting about a new invention, to be known as iron felt. It is made of the very best woolen materials, impregnated with the inventor's patented preparation, which gives it 2,220 pounds' power of resistance to every square centimeter (0·3937 inch). The article is most useful for railroads of all kinds. Placed between rails and sleepers, it deadens sound and prevents shocks. The first experiments with the new material were made by the Berlin City Street Railway, over which 300 trains pass daily. The results surpassed the company's most sanguine expectation. Not only was the noise brought down to a minimum, but the wear and tear was materially diminished. It is to be tried on the new roads in Leipsic. Old buildings, and particularly buildings of stone and iron, suffer most from the shocks and noise of passing trains. Such an insulating material seems to be especially adapted for elevated roads.

The Philadelphia Fire Underwriters' Association has decided to grant permission for the use of acetylene gas in liquefied form under pressure for lighting purposes, provided that the pressure of gas on the piping in the building to be assured shall at no time exceed one-quarter pound per square inch, and that the cylinder containing the liquefied gas under pressure and all pressure-reducing and safety devices be located outside of such building, and in a separate building well ventilated to the outer air, but of sufficient strength to protect the apparatus from outside interference and from the weather (especially the sun's rays); and that the supply pipe for the building be provided with a hand valve just inside of the building assured, so that the gas may be entirely shut off from such building. It is also provided that the cylinder containing the liquefied gas under pressure shall be equipped with a safety valve to protect against both excessive pressure and unusual increase of temperature, and that both the pressure-reducing and the safety (mercury) valves shall be provided with vent pipes opening into the outer air; and that no acetylene gas or calcium carbide shall be stored on the premises.—Jour. Franklin Institute.

SELECTED FORMULÆ.

For Sunburn, etc.—

ALKALINE LOTION.

Bicarbonate of soda	2	drachms.
Powdered borax	1	"
Compound tincture of lavender	1½	"
Glycerin	1	ounce.
Rosewater	4	"

Dissolve the soda and borax in the glycerin and rosewater, and add the tincture. Apply with a small piece of sponge two or three times a day. Then gently dry by dabbing with a soft towel.

QUINCE CREAM.

Quince seeds	2	drachms.
Distilled water	10	ounces.
Glycerin	2	"
Alcohol, 94 per cent	1	"
Rosewater	2	"

Boil the seeds in the water for ten minutes, then strain off the liquid, and when cold add to it the glycerin, alcohol, and rosewater.

GLYCERIN CREAM.

White soft soap	2½	drachms.
Glycerin	1½	"
Almond oil	11	"

Well mix the glycerin and soap in a mortar, and very gradually add the oil, stirring constantly until perfectly mixed.

BISMUTH LOTION.

Subnitrate of bismuth	1½	drachms.
Powdered French chalk	30	grains.
Glycerin	2	drachms.
Rosewater	1½	ounces.

Mix the powders, and rub down carefully with the glycerin; then add the rosewater. Shake the bottle before use.

ALMOND CREAM.

Glycerin cream	2	drachms.
Jordan almonds	4	"
Rosewater	5	ounces.
Essential oil of almonds	3	drops.

Blanch the almonds, and then dry and beat them up into a perfectly smooth paste; then mix in the glycerin cream and essential oil. Gradually add the rosewater, stirring well after each addition; then strain through muslin.—Bulletin of Pharmacy.

French Blacking (Jacquard's).—

	Parts by weight.
Freshly calcined animal charcoal	750
Muriatic acid	250
Treacle	1,000
Prussian blue	30
Indian lake	30
Olive oil	500
Total	2,500

Treat the charcoal with the acid, stir in the finely ground Prussian blue and Indian lake, then the olive oil, and finally the treacle. The olive oil may be replaced by a cheaper one. The blacking made from spent charcoal from sugar refineries goes mouldy.—Oils, Colors and Drysalteries.

Nail Cosmetics.—A "nail wash" sometimes used is:

Oxalic acid	30	grains.
Rosewater	1	ounce.

As a varnish or polish use:

Paraffin wax	60	grains.
Chloroform	2	ounces.
Oil rose	3	drops.

—Pharmaceutical Era.

Varnish for Violins, etc.—

Mastic in tears	10	parts.
Dammar, soft white	5	"
Colored turps	100	"
Raw linseed oil	5	"

It is made as follows: A layer of ground glass is placed in a wide bottomed flask, then the 100 parts of the colored turps, then the mastic, and the two left in contact together for several hours, with frequent shaking. The dammar is then added, which takes another twenty-four hours for solution. In winter each period will require to be extended to thirty hours. The oil is then added, and well incorporated with the varnish by frequent shaking. After standing for another fifteen hours in diffused daylight, the whole is filtered through a cotton cloth. The varnish is greatly improved by keeping from six to eight months before use. The red coloring matters are sandalwood deep (Caliatour), dragon's blood, and gamboge for the yellow, mixtures of the three giving any desired tint.—Oils, Colors and Drysalteries.

Swiss Alpine Milk Shake.—

Mint sirup	5	pints.
Fine Rhine wine	2	"
Messina lemon sirup	½	"
French rose cordial	½	"

Mix well together and filter.

For dispensing, put 1½ ounces of this sirup into a tumbler, clean cracked ice half glass, fresh milk enough to fill glass; then shake thoroughly and top off with a piece of mint.

Stove Polish.—The following formula has been used with very satisfactory results by some of our readers: Melt 400 grammes of asphalt on the open fire, allow to cool, break up and dissolve in sufficient oil of turpentine to bring the whole up to 1,000 grammes.

Moth Paper.—

I.

Carbolic acid	1	ounce.
Ceresin	1	"
Naphthalin	2	"

Melt, immerse pieces of bibulous paper, and dry these on plates.

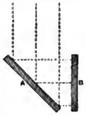
II.

Carbolic acid	1	ounce.
Camphor	1	"
Benzin	to make 1 pint.	

Saturate pieces of blotting paper, and apply, or use the liquid in the form of spray by means of an atomizer.—American Druggist.

ULTIMATE OPTICAL EFFICIENCY.

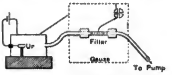
SOME years ago Rayleigh discussed the relative limiting accuracy of the two methods then commonly in use for observing small angular deflections of a suspended system, i. e., the Gaussian method of scale and mirror and the method of the pointer and microscope. The conclusion was reached that theoretically the two systems were on a par with each other when the length of the pointer was equal to the diameter of the mirror. This would give an advantage to the pointer, since that may easily be made ten times as long as the mirror, but in practice this advantage is not maintained. A third method is that based on the interferometer principle, as suggested by Barus and Wadsworth. The latter is of opinion that the smallest movement that can be measured with certainty by this means is that corresponding to a shift of one-twentieth of a fringe. This reduces the estimate of Michelson, who showed that, theoretically, this method of angular measurement may be made from twenty to fifty times as accu-



rate as either of the others referred to. What interferes with the efficiency of the new method is the unsteadiness of the mirrors whose motion lengthens and shortens the path of the interfering beam. Besides, the necessity of two mirrors increases the moment of inertia of the suspended system, and in some cases actually gives the older methods the advantage. Of the two latter, the German method of scale and telescope has the advantage over the English "spot" method, chiefly because of the greater fineness of the reference line (a cross wire in the telescope). A simple way of doubling the efficiency of either method is illustrated in the diagram. The beam is reflected by the movable mirror, A, on to a stationary mirror, B, placed close to it. The latter reflects the beam nearly in the same path, but any angular motion of the mirror, A, produces a motion of four times the amplitude after three reflections. In order to realize the full effect of the aperture of the mirror the two mirrors should be more nearly parallel than shown, and should be as close together as possible.—Wadsworth, Phil. Mag., July, p. 83.

ELECTRIFICATION BY URANIUM.

J. C. BEATTIE has investigated the electrification of air by metallic uranium and its compounds by means of the electric filter method. The filter used was a block tin tube ten centimeters long and one centimeter wide, filled with brass filings. This was insulated on two tunneled pieces of paraffin, and put in metallic connection with the insulated pair of quadrants of a quadrant electrometer of one ten-thousandth microfarad capacity. From one of the pieces of paraffin a metal tube led to an air pump, from the other a piece of India rubber tubing led to the place where the air to be tested was. This air was then drawn through the electric filter, and the deviation of the electrometer reading was noted. The latter showed 0·7 volt as the electrification of the filter by air drawn from the neighborhood of the positive electrode of a Ruhmkorff coil when the terminals were too far apart to allow a spark to pass after one minute of pumping. To examine the electric state of the air in the neighborhood of metallic uranium charged to a given potential, the following experimental arrangement was made: A me-



tallic cylinder was closed at both ends, which were perforated. Air was admitted through one opening, which was plugged with cotton wool, while the other led to the filter. In the cylinder the piece of uranium was placed on a stick of paraffin. No electrification of the air was produced by substituting a piece of lead and charging it up to 95 volts. When the uranium and the copper cylinder were both connected with the sheaths of the electrometer, a deviation of 0·05 volt per minute of pumping was produced. When the uranium was joined to one terminal of a battery, while the cylinder was joined to the other terminal and to the sheath, the electrometer deviation was from + 0·36 to −0·40 volt per minute, when the charge of the uranium was varied between + 93 and −95 volts. Experiments with zinc, aluminum and lead cylinders showed that the nature of the metal did not influence the result. Wrapping the uranium in aluminum foil diminished the electrification, and surrounding it with paraffin wrapped in aluminum stopped it altogether. Similar, though much smaller, electrifications were obtained with uranium acetate and nitrate.—Beattie, Phil. Mag., July, p. 102.

A peculiar method for making castings which are to be partly of hard and partly of soft steel is described in Stahl und Eisen. If a carriage wheel is to be cast with a hard rim, the form is rotated and hard steel poured in. The centrifugal force sends it round the outer edge, so that it forms a rim, and when it is somewhat cooled, the soft steel is added. By this process a very intimate union is obtained, and the wheel is provided with a hard steel rim. The transition from one grade of steel to the other is not gradual, but is sudden.

THE
Scientific American Supplement.

PUBLISHED WEEKLY.

Terms of Subscription, $5 a Year.

Sent by mail, postage prepaid, to subscribers in any part of the United States or Canada. Six dollars a year, sent, prepaid, to any foreign country.

All the back numbers of THE SUPPLEMENT, from the commencement, January 1, 1876, can be had. Price, 10 cents each.

All the back volumes of THE SUPPLEMENT can likewise be supplied. Two volumes are issued yearly. Price of each volume, $2.50 stitched in paper, or $3.50 bound in stiff covers.

COMBINED RATES.—One copy of SCIENTIFIC AMERICAN and one copy of SCIENTIFIC AMERICAN SUPPLEMENT, one year, postpaid, $7.00.

A liberal discount to booksellers, news agents, and canvassers.

THE KLONDIKE GOLD FIELDS.

By H. K. CARROLL, LL.D.

KLONDIKE is a word found neither in dictionary nor gazetteer, and you will look in vain for it in the latest wait for it. They are already on their way to the new country to "stake out" claims, thaw the frozen gravel, dig masses of earth, and "pan out" the "dust." The trail, we are told, is strewn with the bodies of the victims of the craze; and many of the miners who un- The greed of the Spaniards of Pizarro's day for the shining metal was no greater than that which was manifested in the wild rush for California and Australia nearly half a century ago. The news of gold discovery seems to have the power of creating a fever in the

DEPARTURE OF THE "EXCELSIOR," BOUND FOR ST. MICHAELS, CARRYING GOLD SEEKERS.

atlases. A few weeks ago nobody except a few whites and Indians had ever heard of it; now who is there who has not had it on his tongue many times? It has quickly become a magical name, and at its mention golden visions enchant the imagination, and big yellow nuggets and bags of shining dust seem actually to strain the muscles of the hand. The map makers must be diligent and give the world a chart of the new Eldorado. The greedy gold hunters will not, however, covered sudden riches are themselves covered by the soil in which they found the wealth they were never to enjoy.

But crowds will go after gold, anywhere, everywhere, at any cost of suffering and deprivation. They will dig and starve, and even die, amid equatorial heats or polar snows for a handful of yellow earth.

"Gold many handed, sweat and bled for gold,
Waked all the night and labored all the day."

blood, and men, and, in these latter days, women as well, hurry off at mad speed to have their chance, often a very slim one, at fortune.

Where is Klondike? The map given herewith, made from the latest chart prepared by our government, shows that it is in the Queen's dominions, close to the border of our Alaskan possessions. It is in the Northwest Territory, and is, of course, under Canadian control.

It will be observed that it is quite close to the Arctic Circle, whence it may be inferred that its winters, if not its summers, are apt to be rigorous. The summers, beginning in May, are about four months long, and the sun, notwithstanding the high latitude, warms up the atmosphere so thoroughly that sometimes the thermometer climbs above ninety. But surely the nights must be cool, for the gravel, we are told, is frozen down to bed-rock, twenty or twenty-five feet. They might be, if there were any; but for months the people of that region never lose sight of the sun, and at midnight, if it is proper to use such a term, it is almost as light as at noonday.

The country is not entirely barren. Parts of it grow a species of pine which attains a size suitable for boards

and building purposes, and there is a small sawmill at Dawson City to turn out materials for houses. We are also told that miners have had some success in planting gardens. There is little or no game, however, and there does not seem to be an abundant supply of fish in the numerous streams. The Klondike, they tell us, signifies to the Indian "plenty of fish." There is nothing to sustain life except the supplies, mostly of canned goods, which are brought from the towns of British Columbia or of the United States; and since the great rush of prospectors to these valleys, rich only in mineral wealth, food has commanded enormous prices. No article is sold for less than fifty cents, and a bag of flour or a peck of potatoes is sometimes considered a fair equivalent for several ounces of gold.

The Klondike is one of a number of creeks which empty into the Yukon, and gold is found in the gravel deposits which form the valleys through which these streams run. The richest finds have been on the Klondike and the Bonanza; but claims have been laid out also on Dominion, Indian, Hunter, Glacier, Miller, Eldorado and Gold Bottom Creeks. This is nearly all in British territory. But we have gold fields just across the border in our own Territory of Alaska. There are paying mines at Circle City on the Yukon, at Forty Mile, at the junction of Forty Mile Creek with the Yukon, and probably on other streams to the south.

The discovery of the wonderful deposits in the Klondike region appears to have been made in August, a year ago, by George Cormack. Evidently he was not succeeding at "Forty Mile," which is on the Yukon, in Alaska, and strolled across the border on a prospecting tour. He found gold in paying quantities near the junction of the Bonanza and Klondike Creeks, and returned to Forty Mile for help. With two Indians he was able to "pan out" about $500 a week. The news was slow in reaching Circle City, a large camp of miners about two hundred miles lower down on the Yukon. Perhaps they did not believe the first reports. At all events, it was December before any movement was made. Then in one day Circle City was depopulated and a new city, Dawson, was established at the mouth of the Klondike, on the Yukon. There was a mad rush for the new country. Immediately it was all staked out. Along every stream and in every gulch claims were marked off, and with feverish haste the work of thawing the gravel was begun. There was then no water to wash the dirt with; but they could not wait for summer to loose the streams, so some of them made "rockers" and tunneled and "rocked" the earth and found it full of gold.

The stories of how gold was taken in winter and the present summer everybody has read. One man worked a hundred feet of his claim, took out $100,000, refused $200,000 for the rest of it, and started for California. He got as much as $212 from one pan of dirt. He washed out, on the average, $250 an hour. Two men took out $6,000 in one day. Some made no attempt to work their claims, but sold them for moderate fortunes. One miner, who dug down to bed-rock, found that the lowest stratum was lined with gold dust and nuggets. The rock was full of V shaped seams, and every seam contained a clay rich with gold. One of the miners had his wife with him, and she carried gravel to their hut by the panful, and washed it. She took out on her own account $6,000 during the winter. Another woman, not oppressed with household cares or the demands of society, picked up several thousand dollars' worth of nuggets on the dumps—a nice little sum of pin money. Four young men cleaned up $40,000, and a Michigan man, with a few helpers, made $94,000 out of his winter's work. But he had a hard time of it at first. He settled on the Klondike alone. For a place to sleep and keep his provisions he dug a hole in the ground. Every day he tramped about vainly looking for gold. His back was a mass of sores from the heavy pack he carried, and his feet were frozen and blistered. For six weeks he did not see one of his own kind. One day he found a little stream flowing down the mountain side and emptying into a basin. The water was only partly frozen. It was shallow, and at the bottom his aching eyes suddenly caught the gleam of gold. Leaping into the icy water, he began to snatch up the golden nuggets. He worked with wild excitement, and carried the gold to his hut, where he buried it for fear of thieves. He toiled this way until spring and had his fortune. Everybody got gold. If they had no claim and no money to buy one, they got work at from $15 a day up to $50; for labor was scarce. A young man "panned out" $40,000 in two days. Almost every miner got a fortune. Nearly all were poor when they went there, but many came away rich. A deck watchman on one of the river steamers spent a few months on the Klondike, and came to San Francisco with $150,000.

These stories, which seem fabulous, are known to be true. The gold has been brought back and put in banks and assay offices and with trust companies. The miners brought it in carpet bags, sacks, oil cans, old tomato cans, boxes, belts and other queer receptacles. It is estimated that $3,000,000 was taken out in the Yukon district in 1895, nearly $5,000,000 in 1896 and that the yield for 1897 will be over $10,000,000.

The mines are what are known as placer mines, and gold is obtained in the form of dust and nuggets. The largest nugget found so far was worth about $250 and was about the size of an ordinary potato. This is small compared with the nuggets found in Australia and California. The Victorian mines produced a single mass of gold worth $41,000 and weighing 146 pounds avoirdupois, while California broke the record with a lump weighing 186 pounds. California gold is richer than the Klondike metal, having a smaller percentage of silver, lead and other metals. It is the quantities that Klondike yields that makes it one of the most famous gold regions known to the world. Another remarkable feature of the new Eldorado is that none of the claims worked so far has proved a blank. The best claims are those on the Klondike, which empties into the Yukon, the Bonanza, a tributary of the Klondike, and the Eldorado, which flows into the Bonanza. The gold region is believed to embrace Circle City and Forty Mile, Alaska, and the Klondike region south to Stewart River; and it is reasonably certain that we shall yet have large mineral wealth from our Alaskan territory to compensate us for the gradual loss of the fur seal industry.

The great question since the discoveries has been how to get to Klondike. The stream of travel follows two routes principally. Taking steamer at Seattle, Washington, Vancouver or Victoria, British Columbia, you go west to the southwestern extension of Alaska, passing from the Pacific Ocean through Unimak Strait into Bering Sea, and thence to St. Michael Island, some ninety miles above the mouth of the Yukon. There are light draught river steamers which will take you up the Yukon to the gold fields, distant about 2,000 miles. Counting the sea voyage from Seattle to St. Michael, 3,500 miles, makes the gold region some 5,500 miles away by this route. Another route, shorter by at least 2,500 miles, is by steamer from Seattle or Tacoma to Sitka, thence to Juneau and to Dyea, which is on Chilkoot Inlet, at the foot of Chilkoot Pass. From Chilkoot Pass to the Klondike it is about 600 miles. Crossing the mountains is a difficult and hazardous feat. To get over the pass requires an ascent of 4,000 feet, and much of the rise is so precipitous that a single misstep may mean sudden destruction. From the pass the way lies through a chain of five lakes—Lindemann, Bennett, Tagish, Marsh and Labarge—and thence to the head waters of the Yukon. Part of this hard journey is overland, and has frequently to be made through melting snows. Dangerous cataracts are encountered in the boat passage on the lakes, and many wrecks bear witness to the necessity of skillful piloting down the swift currents to Miles Cañon and the White Horse Rapids,

ON THE SUMMIT OF CHILKOOT PASS.

frequently called "the Miner's Grave." This, being a third shorter than the St. Michael route, is selected by ninety out of every hundred miners, notwithstanding its great hardships and perils, for they are naturally in a hurry to get at the nuggets.

Still another way of reaching Klondike is over the White Pass, from Juneau. Ocean steamers can land at the foot of the pass on Skaguay Bay, about eighty-five miles from Juneau. The pass is not difficult. It is 1,000 feet lower than Chilkoot, and it is in contemplation to build a railroad over it to Teslin Lake, a distance of only about thirty-five miles. Light draught steamers will run from Teslin Lake to Grand Canon, around which a road may be built. From the foot of the canon steamers may easily reach all the mining settlements. Within a few months this route will probably be the favorite one, and, of course, a telegraph line will connect Dawson City with the rest of the world at an even earlier date.

And so a trip to the Klondike gold fields may soon be an ordinary vacation tour. For gold is wealth, and wealth men covet, and think no enterprise too great or hazardous to get it. But at present it is no vacation tour; and the hazard is so great that only the strongest and the best equipped should risk starving or freezing to death.

For the article and map we are indebted to the Independent and for our illustrations to the Wave, of San Francisco, Cal.

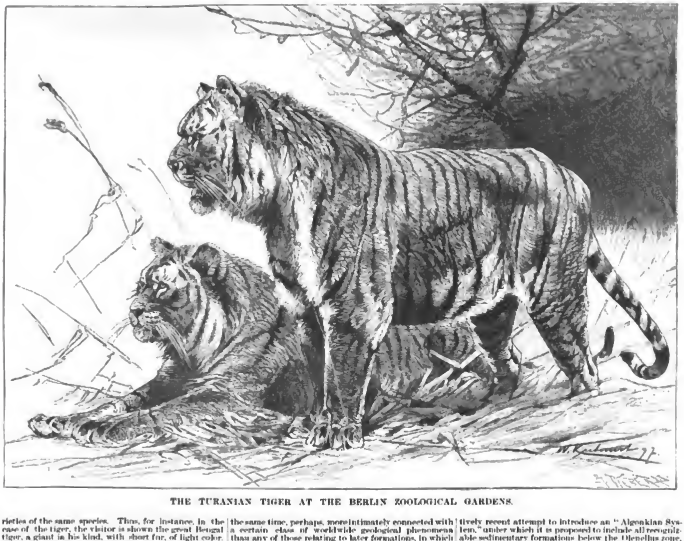
THE TURANIAN OR ARAL TIGER IN THE ZOOLOGICAL GARDENS AT BERLIN, GERMANY.

THE Berlin Zoological Gardens have for some time endeavored to bring before the public geographical varieties of the same species. Thus, for instance, in the case of the tiger, the visitor is shown the great Bengal tiger, a giant in his kind, with short fur, of light color, the dark stripes fairly wide apart; then the Sunda tiger, as found in Malacca and the great Sunda Islands, much smaller than his Bengal relative, of low stature, dark color, and close striped, long fur. He has a bushy beard and often rudiments of a mane. Then, again, there is the Siberian tiger, from the valley of the Amoor River. He resembles the Bengal tiger in his massive body, but differs widely from him in his soft woolly coat and his arm-thick tail.

Quite recently the gardens have received a most interesting addition to their stock in a pair of Turanian or Aral tigers. These are altogether a novelty. There we have the color and the marking of a tiger, but not a tiger's build. The body is comparatively short and deep. The head, particularly of the male, is so short that one is almost inclined to believe that this is a case of accidental deformity. The thick, long coat, which is almost shaggy in some regions, somewhat obliterates the marks, such as the tiger of the tropics shows them. Similarly, the stripes on the tail are somewhat indistinct and irregular. The short mane and the pointed beard forcibly remind us of the Sunda tiger.

Regarding the peculiar formation of the face, Herr Hagenbeck, who imported the animals, asserts that not only the Persian tiger, but also the Persian lion is thus distinguished, and he intends to prove the truth of his assertions by further importation. Scientific literature seems to offer some indications showing that the fossil tiger of the Siwalik Hills (Felis cristata) was similarly flat faced.

Little is known about the new inhabitants of the Berlin Zoological Gardens, except that they reached their present abode via Tiflis, and that probably they are natives of the Aral-Caspian region. A comparison of the animals with some furs obtained by Von Humboldt in those parts, and presented to the Berlin Museum, seems to justify this supposition. Of other zoological institutions, that of St. Petersburg, with its rich stock of Asiatic curiosities, is the only one that is likely to be able to furnish any parallel to these Aral tigers. The appearance of these, and a pamphlet published about them by Mr. Matchie, has created some sensation among zoologists and paleontologists, as supplying some clew in the long debated question on the cave lion and the cave tiger, the remains of which are often found in diluvial strata of Württemberg and other places. For our engraving and the foregoing description we are indebted to the Illustrirte Zeitung.



THE TURANIAN TIGER AT THE BERLIN ZOOLOGICAL GARDENS.

THE BRITISH ASSOCIATION—ADDRESS IN GEOLOGY.

THE address in Section C was delivered by Prof. G. M. Dawson, C.M.G., F.R.S., who said: The nature and relations of the more ancient rocks of North America are problems particularly Canadian, for these rocks in their typical and most easily read development either constitute or border upon the Continental Protaxis of the north. The questions involved are, however, at the same time, perhaps, more intimately connected with a certain class of worldwide geological phenomena than any of those relating to later formations, in which a greater degree of differentiation occurred as time advanced. A reasonably satisfactory classification of the crystalline rocks beneath those designated as Paleozoic was first worked out in the Canadian region by Logan and his colleagues—a classification of which the validity was soon after generally recognized. The greatest known connected area of such rocks is embraced within the borders of Canada; and if I mistake not, the further understanding of the origin and character of these rocks is likely to depend very largely upon work now in progress or remaining to be accomplished here. Although it is intended to speak chiefly of the distinctively pre-Cambrian rocks of Canada, and more particularly of the crystalline schists, it will be necessary also to allude to others, in regard to the systematic position of which differences of opinion exist. Of the Cambrian itself, as distinguished by organic remains, little need be said; but it is essential to keep in touch with the paleontologically established landmarks on this side, if for no other reason than to enable us to realize in some measure the vast lapse of time, constituting probably one of the most important breaks in geological history, by which the Cambrian and its allied rocks are separated from those of the Huronian and Laurentian systems. In attempting to review so wide a subject, and one upon which so much has already been written, the chief difficulty is to determine how much may be legitimately eliminated while still retaining the important features. This must be largely a matter of individual judgment, and I can only hope to present what appear to me to be the essential points, with special reference to the geology of Canada. The useful object of any such review is, of course, to bring out what may now actually be regarded as established respecting these older rocks, and in what direction the most hopeful outlook exists for improving our knowledge of them. For this purpose, the best mode of approaching the subject in the first place, and up to a certain point, is the historical one; and it will thus be desirable to recapitulate briefly the first steps made in the classification of the crystalline schists in Canada.

Having done that, Dr. Dawson concluded: In thus rapidly tracing out what appears to me to be the leading thread of the history of the pre-Cambrian rocks of Canada, and in endeavoring to indicate the present condition of their classification, and to vindicate the substantial accuracy of the successive steps taken in its elaboration, many names and alternative systems of arrangement proposed at different times, by more or less competent authorities, have been passed without mention. It has also been my object, in so far as possible, by omitting special reference to divergent views, to avoid a controversial attitude, particularly in respect to matters which are still in the arena of active discussion, and in regard to which many points remain admittedly subject to modification or change of statement. But, in conclusion, and from the point of view of Canadian geology, it is necessary to refer—even at the risk of appearing controversial—to the comparatively recent attempt to introduce an "Algonkian System," under which it is proposed to include all recognizable sedimentary formations below the Olenellus zone, assumed for this purpose to be the base of the Cambrian. If in what has already been said I have been able correctly to represent the main facts of the case—and it has been my endeavor to do so—it must be obvious that the adoption of such a "system" is a retrograde step, wholly opposed, not only to the historical basis of progress in classification, but also to the natural conditions upon which any taxonomic scheme should be based. It not only detaches from the paleozoic great masses of conformable and fossiliferous strata beneath an arbitrary plane, but it unites these, under a common systematic name, with other vast series of rocks, now generally in a crystalline condition, and includes, as a mere interlude, what, in the region of the Protaxis at least, is one of the greatest gaps known to geological history. In this region it is made to contain the Keweenawan, the Animikie, the Huronian, and the Grenville series, and that without in the least degree removing the difficulty found in defining the base of the last mentioned series. It thus practically expunges the result of much good work, conducted along legitimate lines of advance during many previous years, with only the more than doubtful advantage of ena-

bling the grouping together of many widely separated terranes in other districts where the relations have not been even proximately ascertained. It is, in effect, to my mind, to constitute for geology what was known to the scholastic theologians of a former age as a limbo, appropriate as the abode of unjudged souls and unbaptized infants, that might well in this case be characterized as "a limbo large and broad." It is not intended to deny that there may be ample room for the introduction of a new system, or perhaps, indeed, of an entire geological æon between the Huronian, as we know it in Canada, and the lowest beds which may reasonably be considered as attaching to the Cambrian, or even to the Paleozoic as a whole. On the contrary, what has already been said will, I think, show that in the region of the Protaxis we might very reasonably speak of an "Algonkian hiatus," if we elect so to call it. Elsewhere it will undoubtedly be possible, sooner or later, to designate series of rocks laid down during the time represented only by orogenic movements and vast denudation in the province here more particularly referred to, but before any general systematic name is applied to such terranes they should be defined, and that in such a way as to exclude systems already established as the result of honest work.

THE MOUNT ETNA OBSERVATORY.

ETNA, the largest volcano of Europe, in the form of an imposing isolated cone, one and three-quarter miles in height and eighteen miles wide at the base, is situated upon the eastern coast of Sicily, eighteen miles to the north of Catania. Its summit nearly touches the limit of perpetual snow, and, consequently, in all seasons except summer, the upper portion of the mountain is covered with a mantle of snow of greater or less extent, and the temperature is very cold there. At the bottom, on the contrary, the climate is mild, and there is a varied and luxuriant vegetation consisting of species belonging to both subtropical and cold countries. In fact, in ascending, we met with cactuses, orange and olive trees, grapevines, wheat, chestnut trees, pines, ferns, etc., up to 6,500 ft., after which there is nothing but rocks, volcanic sand and snow. The foot of Etna is one of the most picturesque of regions, and one of the most fertile and populous in the world, despite the threatenings and dangers of the volcano. In the highest part the snow and hail are in perpetual contrast with the heat and fire of the volcano. Usually, the burning materials ejected by Etna melt the snow. Thus, in the winter and spring of 1888, the craters and the lava of the eruption of 1892, that is to say, several months after their cooling, were seen standing out in dark relief against the white background of snow that covered the mountain.

But it requires a stratum of volcanic ashes to protect the snow from the burning heat of the lava at a temperature of 1,000°, so that the latter may not flow over the snow without melting it, except in small quantity. This was observed in the eruption of 1879. This protective or isolating action of the volcanic products has an important industrial application in the commerce of the snow that is preserved, either naturally in the ancient extinct eruptive material or in the artificial trenches that are covered with volcanic sand.

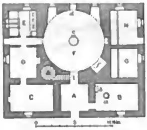


FIG. 1.—Ground Floor Plan of the Etna Observatory: A. Entrance. B. Geodynamics: a, tromometer; b, seismoscopes. C D. Alpine lodgings. E. Kitchen. F. Hall: c, seismic clock. G H. Stable. I. Stairway to the first story. First Story: F. Refractor room. D. Meteorological window; photography. E. Keeper. E. Workshop. G. Bedroom. H. Second room.

From the summit of Etna there is a superb view of 130 miles radius over almost the whole of Sicily, Malta and the Æolian Islands, because the air, reduced to nearly a third of its density, is of extreme transparency.

Etna has long periods of calm, during which the abundant eruptions of steam are rare, and the earth, even near the central crater, at the observatory, is entirely quiet, and does not disturb the most sensitive seismic apparatus.

It may be said that the summit of Etna is an astronomical and meteorological station, placed under exceptionally favorable conditions. At intervals of a few years, this peace is interrupted by terrible paroxysms in which the mountain and its surroundings are violently shaken. The volcano usually opens at the sides, vomits up its contents, throws out blocks that are sometimes 30 cubic feet in volume, and ejects torrents of incandescent lava that enters, burns and buries the forests, vineyards and fields that it meets with in its fatal flow of several miles. Usually, from the summit of Etna, it is possible to follow these grand phenomena, which develop beneath the feet of the observer.

The utility and interest of placing a refuge for visitors and a station for special geological, seismological and geophysical studies upon the summit may be readily seen.

M. Ricco, the learned director of the two observatories of Catania and Etna, who has published such fine works upon this establishment and upon the meteorology of this region, has been kind enough to send us the photographs that illustrate the following note by M. H. Faye, the illustrious dean of French astronomers.

This observatory, says M. Faye, was constructed according to the ideas of Prof. Tacchini, in view of special researches without continuity. It was restored in 1891, after disasters caused by the elements and the eruption of 1886. At present there are in place an equatorial of 18 ft. focal length and various meteorological and seismological instruments. Observations are made here regularly, save in winter, the epoch at which eruptions are inevitable.

This year either a telegraph or telephone line will be run at least as far as to Nicolosi, and this will permit of rendering the work regular. The spot is reached from Catania by a road passable for vehicles as far as to Nicolosi (2,300 ft.), and by mule road up to Casa del Bosco (4,700 ft.), and to the Alpine meteorological station (6,140 ft.), and then by more or less visible and practicable footpaths.

FIG. 2.—ALPINE METEOROLOGICAL STATION HALF WAY BETWEEN NICOLOSI AND THE ETNA OBSERVATORY.

FIG. 3.—CENTRAL CRATER OF ETNA AND VULCAROLO SEEN FROM THE OBSERVATORY (SOUTH).

In summer persons come by mule up to the very door of the observatory. In winter the mules very rarely go beyond Casa del Bosco, and the rest of the journey is performed upon the snow, which is usually soft and fatiguing to walk over. The observatory is then buried under 6 to 15 ft. of snow, so that it has to be entered through a window in the first story. It may be said that the enemy is not the volcano, but the snow. Moreover, there is no mountain sickness from which one cannot rid himself by habituation.

The position of the observatory is as follows:

Altitude	9,650 feet.
Latitude	37° 44′ 3″
Longitude, east	2° 33′ 8″ (Rome).

FIG. 4.—THE ASTRONOMICAL OBSERVATORY ON THE SUMMIT OF ETNA (9,652 FEET).

It is situated at about half a mile from the southern edge of the central crater, which is 10,860 ft. in height, and, consequently, overlooks the observatory 1,216 ft. to the north-northwest.

From the meteorological observations made since 1892, the following data have been obtained:

	Mean temperature.
Winter	— 0·6°
Spring	— 1·5°
Summer	+ 7·3
Autumn	+ 2·7
Year	+ 0·4°

Annual means of other meteorological data:

Pressure	558·9 mm.
Tension of vapor	3·2 "
Relative humidity	65
Prevailing wind	N.E.
Precipitation	37 days.

The calculated temperature of the summit should be 3·2° lower than that noted at the observatory. The direct measurement of such temperature gives 0·6° more. This is the effect of reheating due to the crater.

The spectroscopic observations have given the following averages, reduced to the normal mass of the atmosphere traversed:

	Observatories. Etna.	Catania.
Thickness of the atmospheric band, a	1·7	1·4
Intensity of the zone, δ	0·5	0·1
Intensity of the rain band	0·5	1·2

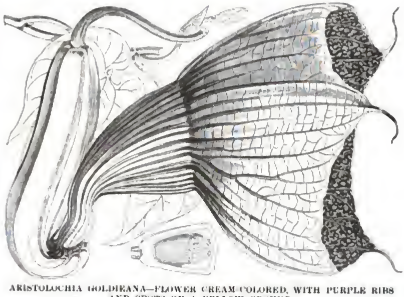
Electric manifestations upon Etna are rare and occur mainly in autumn. It is not certain that lightning has struck the Casa Inglese once since 1810.

The Etna observatory, which is built over that old hut, has never been struck, although there is no lightning rod, and the great metallic mass of the cupola and roof are deprived of all communication with the ground. This rareness does not seem to depend upon that of the aqueous vapor, since upon the Alps, where such vapor is still rarer, there are often imposing electric manifestations. With Etna, we certainly have to take into account the protective action of the central crater, the great plume of smoke and hot steam of which acts silently like a gigantic lightning protector. —La Nature.

FIG. 5.—ETNA AND THE OBSERVATORY AS SEEN FROM THE CATANIA OBSERVATORY.

ARISTOLOCHIA GOLDIEANA.

ONE of the most extraordinary flowers in bloom in the Victoria house, Kew, is this West African species. The flower is naturally pendulous, or nearly so, the lower part of the tube is irregularly cylindrical, cream-colored, smooth, and bent upward nearly at a right angle into a funnel-shaped upper half. This part of the tube is marked with prominent purple ribs, and expands into a bowl-shaped three-lobed limb, strongly marked with purplish ribs, the three lobes prolonged into acuminate points; the interior of the bowl is yellowish, thickly marbled with velvety purplish brown spots. The entire flower is as large as one's hat, and very striking in appearance, just one of those interesting plants which the floral committee would pass over as of no commercial value. Although in point of size, form and color it is very attractive, we cannot say so much for its odor.—Gardeners' Chronicle.



ARISTOLOCHIA GOLDIEANA—FLOWER CREAM-COLORED, WITH PURPLE RIBS AND SPOTS ON A YELLOW GROUND.

EXPLORATIONS OF THE UNIVERSITY OF PENNSYLVANIA IN BABYLONIA.*

THIS fine volume, to be followed by its mate, telling the story of the first great expedition for excavation in old Babylonia, sent from the United States by the University of Pennsylvania, is not published by the university, as might have been expected, but by a New York firm. With a good deal of confidence we assume that the reason is that Dr. Peters, as director of that expedition, having left his position as a teacher in the university to become the rector of a large New York church, in lineal succession to his father and grandfather, does not care to have his work supervised by the scholar, no matter how able, who edits for the university its publications on the expedition, and who was, during the years here described, his subordinate. Dr. Peters can thus speak with a certain freedom which has its advantages and disadvantages.

Dr. Peters was the natural leader of this expedition. He was not only active in proposing the preliminary Wolfe expedition to Babylonia, in the years 1884-85, led by Dr. Ward, but by interesting Bishop Potter, and through him Miss Catherine Wolfe, in the subject, he secured the $5,000 which made that expedition possible. It was Dr. Peters' energy which secured the funds for a more ambitious expedition, through liberal friends of the University of Pennsylvania, with which Dr. Peters was then connected as professor of Hebrew, as well as with the Episcopal Seminary in Philadelphia. To these public-spirited gentlemen, among whom we may mention the brothers E. W. and C. H. Clarke, he dedicates this volume.

Dr. Ward had rapidly visited all the important sites in Babylonia, with the exception of Sifr, Larsa and Abu Sharein, and had specially recommended Niffer or Nuffar (the ancient Nippur) as a site for exploration by an American expedition. After full study Dr. Peters selected this site for excavation, and its name is given to this volume. Work has been carried on there since 1889, the first two years under Dr. Peters.

It is the story of these first two years which Dr. Peters is to tell, only the first year's story being in this volume. The succeeding years belong to the self-denying work of Mr. J. H. Haynes, who remained alone on the hill with his Arabs summer and winter, and whose volume of description, edited very fully by Dr. Hilprecht, is in preparation, to be published by the university. Two volumes of texts discovered by the expedition have already been issued by Dr. Hilprecht, and have proved of the first importance historically.

The first year was one of disappointment and disaster. The funds were freely supplied; tried assistants were secured in the persons of Mr. Haynes and Mr. D. Z. Noorian, interpreter and director of the workmen, both of whom had accompanied the Wolfe expedition, and two young Assyriologists, Dr. Hilprecht and Dr. R. F. Harper—really one too many—and Mr. P. H. Field as architect and surveyor. With them, at his own expense, was Mr. J. Dyneley Prince, who went as far as Bagdad, where he was compelled by sickness to leave the expedition. Dr. Peters is frank enough to say:

"Our first year at Nippur had ended in failure and disaster. I had failed to win the confidence of my comrades. None of them agreed with me in my belief in the importance of Nippur, and the desirability of excavating down to the foundations. The Arabs had proved treacherous. The Turkish authorities disbelieved our story of Arab treachery, and suspected us of plotting with our Turkish commissioner to carry away antiquities. I was sick and nervous, having suffered for two months almost incessantly from severe facial neuralgia and consequent sleeplessness. In fact, I was on the verge of collapse, and the world had never seemed quite so black before."

Indeed, things were black. An Arab thief had been shot by their Turkish soldier. Dr. Peters had mistakenly refused to pay blood money. The Arabs had burned their camp and robbed them of twelve hundred dollars in gold; they were escaping in danger of their lives, some of their horses having been burned. Turks as well as Arabs were hostile. All the American members had sent in their resignations. Dr. Peters was recalled to Philadelphia, and the whole expedition was likely to be given up and to end in failure. It is to the great credit of the gentlemen connected with the university that they decided to continue another year with a smaller force, consisting only of Dr. Peters, Mr. Haynes and Mr. Noorian. The result of that decision was a success which has received the warmest recognition of the best European scholars. It is useless to deny that the disaster of the first year—apart from the failure to reach the valuable antiquities—was due in part to inexperience, and in part to what is included under the general term of incompatibilities. Success in dealing with Arabs requires knowledge of their character, and an avoidance of any apparent suspicion of them. The lack of these conditions has wrecked not a few expeditions in which young, eager and positive men have been thrown into relations intimate enough to produce other than friendly feelings. This volume suggests and sometimes exposes the personal infelicities of the first year. Some words about Dr. Peters' companions might quite as well have been omitted. We shall be surprised if they do not provoke unpleasant rejoinders.

Of the difficulties experienced in securing a firman we need not speak. Most of the volume is taken up with the story of the delay in Constantinople and the journey down the Euphrates, along routes traversed by many travelers. The one important discovery recorded is the identification of Kal'at Dibse with the biblical Tiphsah and the classical Thapsacus. This, we believe, is new, and needs, as Dr. Peters suggests, further investigation, especially as of the four consonants in Tiphsah only one appears in Dibse, which has precisely the consonants of the Hebrew and Arabic word for honey or sirup, so that one would naturally suppose Kal'at Dibse to mean the Village of Date Sirup, Dibse being for dibs. Yet that the corruption might come by volksetymologie from Tiphsah we would not deny, if the locality fits as well as is said.

It is not an eventful story which Dr. Peters tells of his trip down the Euphrates. It is a region traveled over by many armies and many voyageurs, but no one yet has explored it, as Edward Robinson did Palestine, with a previous knowledge of the entire history and literature of the region, Greek and Arabic, so as to be able on the spot to know what old sites are to be located. The most careful subsequent study in libraries will not compensate for the cursory traveler's necessary ignorance at the time. Doubtless Dr. Peters would be glad to visit the country again with better educated eyes. As it is he has supplemented his necessarily hasty notes of daily movement with historical and geographical information derived chiefly from Ainsworth, Chesney, Procopius, etc. Strangely, he does not find Cernik of any value, and does not mention him except briefly in an appendix. We should have supposed his "Studien-Expedition" to be of the highest value topographically, as its map is certainly the best we have of this part of the valley. There were no adventures more exciting than one of the company falling into the Euphrates, nothing certainly so serious as Ainsworth's being left behind by his steamer and having to walk fifty miles under the guidance of Arab robbers before he overtook his party.

The real interest of the volume begins, of course, near its end, when the party reached Niffer and began their excavations. Sixty pages are given to the two and a half months which constituted the first campaign that ended so disastrously, the camp burned, the money stolen, the Arabs furious, almost nothing discovered, the expedition broken up by the resignation of its members, and its director recalled to Philadelphia. Perhaps a fuller account of these dozen weeks would have been interesting, even at the expense of reducing the observations about Constantinople and the journey, but the scientific results, which were secured the next year, will come in the second volume. The failure of the first year, which Dr. Peters can afford

* "Nippur; or, Explorations and Adventures on the Euphrates." The Narrative of the University of Pennsylvania Expedition to Babylonia in the years 1888-1890. By John Punnett Peters, Ph.D., Sc.D., D.D., Director of the Expedition. With illustrations and maps. Volume I, First Campaign. 8vo, pp. xv, 375. G. P. Putnam's Sons, New York.

distinctly to acknowledge, had its causes, which he has partly intimated, and, we judge, partly withheld. Each member of the expedition would tell his own story. Dr. Peters, on whom the chief responsibility rested, deserves the credit of great determination and of the final victory over difficulties. He was able to go back the second year, conquering all adverse circumstances, and with fewer companions achieved at last a great success. The story he tells is of much interest, and the volume a valuable addition to the history of Oriental exploration.

We are not quite satisfied with the illustrations; but it is not Dr. Peters' fault that so many of the photographs taken in his expedition failed to develop. Most of the valuable pictures are from the photographs of the previous Wolfe expedition, for which general credit is given in the introduction. Of the other pictures we note as specially interesting the framework of an Affech hut of reeds and mats and one of the two pictures of the excavations.

In an appendix, following the Turkish irade authorizing the expedition, and other documents, are sixty pages of extracts from Dr. Ward's diary, taken on the Wolfe expedition. It was his intention to prepare a volume on that expedition, which was solely one of rapid survey, to learn whether such an expedition as that led later by Dr. Peters would be feasible, and to recommend sites for exploration. Other duties prevented him from carrying out his literary purpose, and he put his diary at the service of Dr. Peters, who was compelled to abridge it, omitting diagrams and what seemed to him less important, but retaining the numerous records of angular bearings taken from the various mounds, which ought to be of great value in constructing a map, inasmuch as no map exists of value for the region south of that so carefully plotted by Collingwood and Bewsher.—The Independent.

ADDRESS BY SIR JOHN EVANS,

K.C.B., D.C.L., LL.D., Sc.D., Treas. R.S., V.P.S.A., For. Sec. G. S.; Correspondant de l'Institut de France, etc.; President of the British Association for the Advancement of Science.*

In his address to this association at the Bath meeting of 1864, Sir Charles Lyell struck so true a note that I am tempted to reproduce the paragraph to which I refer:

"When speculations on the long series of events which occurred in the glacial and post-glacial periods are indulged in, the imagination is apt to take alarm at the immensity of the time required to interpret the monuments of these ages, all referable to the era of existing species. In order to abridge the number of centuries which would otherwise be indispensable, a disposition is shown by many to magnify the rate of change in prehistoric times by investing the causes which have modified the animate and inanimate world with extraordinary and excessive energy. It is related of a great Irish orator of our day that when he was about to contribute somewhat parsimoniously toward a public charity, he was persuaded by a friend to make a more liberal donation. In doing so he apologized for his first apparent want of generosity by saying that his early life had been a constant struggle with scanty means, and that 'they who are born to affluence cannot easily imagine how long a time it takes to get the chill of poverty out of one's bones.' In like manner we of the living generation, when called upon to make grants of thousands of centuries in order to explain the events of what is called the modern period, shrink naturally at first from making what seems so lavish an expenditure of past time. Throughout our early education we have been accustomed to such strict economy in all that relates to the chronology of the earth and its inhabitants in remote ages, so fettered have we been by old traditional beliefs, that even when our reason is convinced, and we are persuaded that we ought to make more liberal grants of time to the geologist, we feel how hard it is to get the chill of poverty out of our bones."

Many, however, have at the present day got over this feeling, and of late years the general tendency of those engaged upon the question of the antiquity of the human race has been in the direction of seeking for evidence by which the existence of man upon the earth could be carried back to a date earlier than that of the quaternary gravels.

There is little doubt that such evidence will eventually be forthcoming, but, judging from all probability, it is not in northern Europe that the cradle of the human race will eventually be discovered, but in some part of the world more favored by a tropical climate, where abundant means of subsistence could be procured and where the necessity for warm clothing did not exist.

Before entering into speculations on this subject or attempting to lay down the limits within which we may safely accept recent discoveries as firmly established, it will be well to glance at some of the cases in which implements are stated to have been found under circumstances which raise a presumption of the existence of man in pre-glacial, Pliocene or even Miocene times.

Flint implements of ordinary paleolithic type have, for instance, been recorded as found in the eastern counties of England, in beds beneath the chalky bowlder clay; but on careful examination the geological evidence has not to my mind proved satisfactory, nor has it, I believe, been generally accepted. Moreover, the archæological difficulty that man, at two such remote epochs as the preglacial and the postglacial, even if the term glacial be limited to the chalky bowlder clay, should have manufactured implements so identical in character that they cannot be distinguished apart, seems to have been entirely ignored.

Within the last few months we have had the report of worked flints having been discovered in the late Pliocene forest bed of Norfolk, but in that instance the signs of human workmanship upon the flints are by no means apparent to all observers.

But such an antiquity as that of the forest bed is as nothing when compared with that which would be implied by the discoveries of the work of men's hands in the Pliocene and Miocene beds of England, France, Italy, and Portugal, which have been accepted by some geologists. There is one feature in these cases which has hardly received due attention, and that is the isolated character of the reputed discoveries. Had man, for instance, been present in Britain during the Crag period, it would be strange indeed if the sole traces of his existence that he left were a perforated tooth of a large shark, the sawn rib of a manatee, and a beaming full face carved on the shell of a pectunculus!

In an address to the Anthropological Section at the Leeds meeting of this association in 1890 I dealt somewhat fully with these supposed discoveries of the remains of human art in beds of tertiary date; and I need not here go further into the question. Suffice it to say that I see no reason why the verdict of "not proven" at which I then arrived should be reversed.

In the case of a more recent discovery in Upper Burma in beds at first pronounced to be upper Miocene, but subsequently "definitely ascertained to be Pliocene," some of the flints are of purely natural and not artificial origin, so that two questions arise: first, Were the fossil remains associated with the worked flints or with those of natural forms? And second, Were they actually found in the bed to which they have been assigned or did they merely lie together on the surface?

Even the Pithecanthropus erectus of Dr. Eugène Dubois from Java meets with some incredulous objectors from both the physiological and the geological sides. From the point of view of the latter the difficulty lies in determining the exact age of what are apparently alluvial beds in the bottom of a river valley.

When we return to paleolithic man, it is satisfactory to feel that we are treading on comparatively secure ground, and that the discoveries of the last forty years in Britain alone enable us to a great extent to reconstitute his history. We may not know the exact geological period when first he settled in the British area, but we have good evidence that he occupied it at a time when the configuration of the surface was entirely different from what it is at present; when the river valleys had not been cut down to anything like their existing depth, when the fauna of the country was of a totally different character from that of the present day, when the extension of the southern part of the island seaward was in places such that the land was continuous with that of the continent, and when in all probability a far more rainy climate prevailed. We have proofs of the occupation of the country by man during the long lapse of time that was necessary for the excavation of the river valleys. We have found the old floors on which his habitations were fixed, we have been able to trace him at work on the manufacture of flint instruments, and by building up the one upon the other the flakes struck off by the primeval workman in those remote times we have been able to reconstruct the blocks of flint which served as his material.

That the duration of the paleolithic period must have extended over an almost incredible length of time is sufficiently proved by the fact that valleys some miles in width and of a depth of from 100 to 150 feet have been eroded since the deposit of the earliest implement-bearing beds. Nor is the apparent duration of this period diminished by the consideration that the floods which hollowed out the valleys were not in all probability of such frequent occurrence as to teach paleolithic man by experience the danger of settling too near to the streams, for had he kept to the higher slopes of the valley there would have been but little chance of his implements having so constantly formed constituent parts of the gravels deposited by the floods.

The examination of British cave deposits affords corroborative evidence of this extended duration of the paleolithic period. In Kent's cavern at Torquay, for instance, we find in the lowest deposit, the breccia below the red cave earth, implements of flint and chert corresponding in all respects with those of the high level and most ancient river gravels. In the cave earth these are scarcer, though implements occur which also have their analogues in the river deposits; but, what is more remarkable, harpoons of reindeer's horn and needles of bone are present, identical in form and character with those of the caverns of the reindeer period in the south of France, and suggestive of some bond of union or identity of descent between the early troglodytes, whose habitations were geographically so widely separated the one from the other.

In a cavern at Creswell Crags, on the confines of Derbyshire and Nottinghamshire, a bone has, moreover, been found engraved with a representation of parts of a horse in precisely the same style as the engraved bones of the French caves.

It is uncertain whether any of the river drift specimens belong to so late a date as these artistic cavern remains; but the greatly superior antiquity of even these to any neolithic relics is testified by the thick layer of stalagmite, which had been deposited in Kent's Cavern before its occupation by men of the neolithic and bronze periods.

Toward the close of the period covered by the human occupation of the French caves there seems to have been a dwindling in the number of the larger animals constituting the quaternary fauna, whereas their remains are present in abundance in the lower and therefore more recent of the valley gravels. This circumstance may afford an argument in favor of regarding the period represented by the later French caves as a continuation of that during which the old river gravels were deposited, and yet the great change in the fauna that has taken place since the latest of the cave deposits included in the paleolithic period is indicative of an immense lapse of time.

How much greater must have been the time required for the more conspicuous change between the old quaternary fauna of the river gravels and that characteristic of the neolithic period!

As has been pointed out by Prof. Boyd Dawkins, only thirty-one out of the forty-eight well ascertained species living in the postglacial or river drift period survived into prehistoric or neolithic times. We have not, indeed, any means at command for estimating the number of centuries which such an important change indicates; but when we remember that the date of the commencement of the neolithic or surface stone period is still shrouded in the mist of a dim antiquity, and that prior to that commencement the river drift period had long come to an end; and when we further take into account the almost inconceivable ages that even under the most favorable conditions the excavation of wide and deep valleys by river action implies, the remoteness of the date at which the paleolithic period had its beginning almost transcends our powers of imagination.

We find distinct traces of river action from 100 to 200 feet above the level of existing streams and rivers, and sometimes at a great distance from them; we observe old fresh water deposits on the slopes of valleys several miles in width; we find that long and lofty escarpments of rock have receded unknown distances since their summits were first occupied by paleolithic man; we see that the whole side of a wide river valley has been carried away by an invasion of the sea, which attacked and removed a barrier of chalk cliffs from 400 to 600 feet in height; we find that what was formerly an inland river has been widened out into an arm of the sea, now the highway of our fleets, and that gravels which were originally deposited in the bed of some ancient river now cap isolated and lofty hills.

And yet, remote as the date of the first known occupation of Britain by man may be, it belongs to what, geologically speaking, must be regarded as a quite recent period, for we are now in a position to fix with some degree of accuracy its place on the geological scale. Thanks to investigations ably carried out at Hoxne, in Suffolk, and at Hitchin, in Hertfordshire, by Mr. Clement Reid, under the auspices of this association and of the Royal Society, we know that the implement-bearing beds at those places undoubtedly belong to a time subsequent to the deposit of the great chalky bowlder clay of the eastern counties of England. It is, of course, self evident that this vast deposit, in whatever manner it may have been formed, could not, for centuries after its deposition was complete, have presented a surface inhabitable by man. Moreover, at a distance but little farther north, beds exist which also, though at a somewhat later date, were apparently formed under glacial conditions. At Hoxne the interval between the deposit of the bowlder clay and of the implement-bearing beds is distinctly proved to have witnessed at least two noteworthy changes in climate. The beds immediately reposing on the clay are characterized by the presence of alder in abundance, of hazel, and yew, as well as by that of numerous flowering plants indicative of a temperate climate very different from that under which the bowlder clay itself was formed. Above these beds characterized by temperate plants, comes a thick and more recent series of strata, in which leaves of the dwarf Arctic willow and birch abound, and which were in all probability deposited under conditions like those of the cold regions of Siberia and North America.

At a higher level and of more recent date than these—from which they are entirely distinct—are the beds containing paleolithic implements, formed in all probability under conditions not essentially different from those of the present day. However this may be, we have now conclusive evidence that the paleolithic implements are, in the eastern counties of England, of a date long posterior to that of the great chalky bowlder clay.

It may be said, and said truly, that the implements at Hoxne cannot be shown to belong to the beginning rather than to some later stage of the paleolithic period. The changes, however, that have taken place at Hoxne in the surface configuration of the country prove that the beds containing the implements cannot belong to the close of that period.

(To be continued.)

* Delivered at Toronto, August 18, 1897.

EDWARD DRINKER COPE, NATURALIST.*

VII.

Cope was not satisfied with the study of morphological details or simple taxonomy. He aspired to know how animals came into existence; why they varied as they did, and what laws determined their being. His was an eminently philosophical mind, but at the same time with a decided tendency to metaphysical speculation. In one of his earliest papers he manifested this tendency and it persisted through life. It is with much hesitation that I venture to give an exposition of his most salient views, for I must confess I do not altogether like his philosophy and am able to subscribe to it only in part. I cannot but wish that one of his numerous disciples could have been chosen for this task. But I must not pass it by, for it is the most characteristic feature of Cope's work and the one he most esteemed.

Cope began his public scientific career, it will be remembered, in the same year in which Darwin's long studies had fructified into his "Origin of Species."

As was quite natural with his keen instincts, Cope early adopted the doctrine of transmutation of species and recognized the truth that all the animals of the present epoch are descendants from those of past times with modifications which separate them as species, and eventually as representatives of genera, of families and orders differing from the earlier ones as we retrace the steps of Time farther and farther back. He was not, however, satisfied with Darwin's theory, and denied that natural selection was a sufficient factor for differentiation. He would not admit that animals were passive subjects and that the slight variations which were manifest in the progeny of species were sufficient to enable Nature to select from and to fit for future conditions. He contended that the volition and endeavors of an animal had much to do with future progeny as well as its own brief life. In short, he claimed that characters acquired by animals through their own efforts or forced on them by various external agencies or accidents might be transmitted to their offspring. He further, first in a chapter in his "Synopsis of the Cyprinidæ of Pennsylvania" outlined, and later, in "The Origin of Genera," he elaborated a peculiar theory characterized mainly by what he called (with Prof. Hyatt) "the law of acceleration and retardation" in development. Darwin complained that he could never understand this law, and Cope complained that Darwin had not stated his views correctly in an attempted abstract. I therefore give Cope's views, restated in his own language, summarizing them years afterward. "The following doctrines," he says, "were taught:"

"First, that the development of new characters has

* Presidential address by Prof. Theodore Gill before the annual meeting of the American Association for the Advancement of Science, August 9, 1897.

been accomplished by an acceleration or retardation in the growth of the parts changed. This was demonstrated by reference to a class of facts, some of which were new, which gave ground for the establishment of the new doctrine.

"Second, that of exact parallelism between the adult of one individual or set of individuals and a transitional stage of one or more other individuals. This doctrine is distinct from that of inexact parallelism, which had already been stated by Von Baer. And that this law expresses the origin of genera and higher groups, because,

"Third, they can only be distinguished by single characters when all their representatives come to be known.

"Fourth, that genera and various other groups have descended, not from a single generalized genus, etc., of the same group, but from corresponding genera of one or more other groups. This was called the doctrine of homologous groups.

"Fifth, the doctrine that these homologous groups belong to different geological periods, and,

"Sixth, to different geographical areas, which, therefore, in some instances, are,

"Seventh, related to each other in a successional way like the epochs of geological time.

"Of these doctrines it may be observed that the first and second are now the common property of evolutionists, and are recognized everywhere as matter of fact. The names which I selected to express them have, however, only come into partial use. The author believes that, although the doctrine was vaguely shadowed out in the minds of students prior to the publication of this essay, it had not previously been clearly expressed nor been reduced to a demonstration. Of the truth of the doctrine the author is more than ever convinced, and he believes that paleontological discovery has demonstrated it in many instances, and that other demonstrations will follow. The fourth proposition (that of homologous groups) is now held as a hypothesis explaining the phylogeny of various groups of animals. For the descent of one homologous group from another, the term polyphyletic has been coined. It remains to be seen whether the doctrine is of universal application or not. That homologous groups belong to different geological horizons, as stated under the fifth head, has been frequently demonstrated since the publication of the essay. That the sixth proposition is true in a certain number of cases is well known, and it follows that the seventh proposition is also true in those cases. The latter hypothesis, which was originally advanced by Prof. Agassiz, is, however, only partially true, and the advance of paleontological study has not demonstrated that it has had a very wide application in geological time.

"A proposition which was made prominent in this essay was that the prevalence of non-adaptive characters in animals proves the inadequacy of hypotheses which ascribe the survival of types to their superior adaptation to their environment. Numerous facts of this kind undoubtedly indicate little or no activity of a selective agency in nature, and do point to the existence of an especial developmental force acting by a direct influence on growth. The action of this force is the acceleration and retardation appealed to in this paper. The force itself was not distinguished until the publication of the essay entitled 'The Method of Creation' [1871], where it was named growth force, or bathmism. The energetic action of this force accounts for the origin of characters, whether adaptive or non-adaptive, the former differing from the latter in an intelligent direction, which adapts them to the environment. The numerous adaptive characters of animals had by that time engaged the attention of the author, and he found that they are even more numerous than the non-adaptive. Some of the latter were accounted for on the theory of the 'complementary location of growth force.'"

We can only consider the "law of acceleration and retardation." Again it behooves us to seek his own definition:

"a. The succession of construction of parts of a complex was originally a succession of identical repetitions; and grade influence merely determined the number and location of such repetitions.

"b. Acceleration signifies addition to the number and location of such repetitions during the period preceding maturity, as compared with the preceding generation, and retardation signifies a reduction of the number of such repetitions during the same time."*

His meaning may best be inferred from his application to mankind. This was done in the following terms in 1872:†

"Let an application be made to the origin of the human species. It is scarcely necessary to point out at the start the fact, universally admitted by anatomists, that man and monkeys belong to the same order of mammalia, and differ in those minor characters generally used to define a 'family' in zoology.

"Now, these differences are as follows: In man we have the large head with prominent forehead and short jaws; short canine teeth without interruption behind (above); short arms, and thumb of hand not opposable. In monkeys we have the reverse of all these characters. But what do we see in young monkeys? A head and brain as large relatively as in many men, with jaws not more prominent than in some races; the arms not longer than in the long-armed races of men, that is, a little beyond half way along the femur, . . . At this age of the individual the distinctive characters are therefore those of homo, with the exception of the opposable thumb of the hind foot and the longer canine tooth. . . .

"Now in the light of various cases observed, where members of the same species or brood are found at adult age to differ in the number of immature characters they possess, we may conclude that man originated in the following way; that is, by a delay or retardation of growth of the body and fore limbs as compared with the head; retardation of the jaws as compared with the brain case, and retardation in the protrusion of the canine teeth."

There is good reason for thinking that fallacy is involved in this argument and that quite a different interpretation should be put on the evolution of the characters in question. It is not the fore limbs that are retarded in man, but the hind limbs have become enlarged (compare the adult and the infant). There is not retardation of the jaws, but a special teleological adaptation. Man has for the most part at least discontinued the use of his teeth for warfare, and as a result of diminished use the canines have become reduced and the diastemata of the dental series been obliterated. The brain has grown after birth and become enlarged, and as a consequence the brain case has extended forward—the reverse of what occurs in the apes. Concomitantly with the diminished use of the teeth and jaws, the masseter and temporal muscles have become reduced and the sagittal and lambdoidal ridges have consequently become atrophied. The ecarinate rounded voluminous calvarium is the result.

It has been claimed that the young of higher species "are constantly accelerating their development." In man, however, development is retarded, inasmuch as infancy and juvenility are prolonged far beyond the periods observed in our simian relatives.

Such examples as this give cause to believe that the "law of acceleration and retardation" has been at least unduly extended. Acceleration and retardation are, however, to a large extent, terms which express facts of evolution; whether the word law is applicable may depend on the meaning one gives the word.

The transmission of acquired characters was one of the accepted and most cherished dogmas of Cope, and the belief in transmissibility of such characters is an essential of the creed of so many who have become his followers in America that a special school came into existence known as the Neo-Lamarckian and also as the American school. My own prejudices have inclined me to that school. Nevertheless, when I have divested myself of such prejudices as well as I could, I have been compelled to admit that the evidence of the heredity of acquired characters was rather weak. There was, indeed, evidence for, as well as against, but that against the doctrine of the transmissibility of acquired characters seems to be the most weighty.

It is to be understood that the acquired characters considered in this connection are such as have been developed during postnatal life as a result of endeavors of the animal or of the influence of external agencies. The evidence presented has been mostly in support of the contention that the characters acquired have been directly inherited by offspring, and consequently the transition from the form not possessing the character to one having it is rapid. The evidence adduced has not been conclusive, to say the least. There is, apparently, a germ of truth in the proposition that acquired characters are transmitted, but in a modified sense, and the case has been weakened rather than strengthened by the evidence offered.

The evidence for inheritance of acquired characters was frequently given by Cope, and in his last published work, "The Primary Factors of Organic Evolution," he marshaled the testimonies of many witnesses with his accustomed skill. He evoked "evidence from embryology," "evidence from paleontology," "evidence from breeding;" he considered the "characters due to nutrition," "characters due to exercise of function," "characters due to disease," "characters due to mutilation and injuries," and "characters due to regional influence;" he inquired into "the conditions of inheritance," and he fought against the "objections to the doctrine of inheritance of acquired characters." I have gone over all this evidence and yet I have not been convinced that the contention has been sustained that characters acquired during the external life of an animal are transmitted. Many cases are alleged to sustain the "inheritance of characters due to mutilation and injuries." Some of these may be considered as mere coincidences; others provoke skepticism for one reason or other. To discuss them would be out of place here. But at least we may meet evidence with counter evidence.

On the one hand, all the data and experiments recapitulated in the cases enumerated concern only two, or at most very few, generations of the animals in question, and were within the compass of a single man's lifetime.

On the other hand, we have data and observations of the most reliable nature, and of an extraordinary compass. These have resulted not from experiments for the determination of a specific question, but from observances of a religious character. They were really in the nature of surgical operations, but for our purpose may be looked upon as experiments and have the value of contrived experiments. In no other field has such a series of disinterested experiments been available. They were conducted on countless millions of mankind and for thousands of years. The subjects experimented upon were kept isolated from others alike by their own prejudices and the prejudices of their neighbors. Circumcision is the term applied to the experiments in question.

For about 4,000 years circumcision has been practiced on a gigantic scale. Every male child among the Jews was operated upon, not only in Palestine, but wherever representatives of the race had wandered and adhered to their religion; religion itself was involved in the operation and it was regarded as a holy rite; the most scrupulous attention was paid to details. The operation was performed eight days after birth, and consequently there could be no functional activity of the tissues concerned. But after 4,000 years the new-born boys of the race come into the world with the special integument developed as much as in those of other races. Even the principle of atrophy through disuse has not become manifest in the case.
